Two-Dimensional Noble-Metal Chalcogenides and Phosphochalcogenides**

Roman Kempt, Agnieszka Kuc, and Thomas Heine*

Keywords:
density functional calculations · noble-metal dichalcogenides · Raman spectroscopy · sensors · two-dimensional materials
Noble-metal chalcogenides, dichalcogenides, and phosphochalcogenides are an emerging class of two-dimensional materials. Quantum confinement (number of layers) and defect engineering enables their properties to be tuned over a broad range, including metal-to-semiconductor transitions, magnetic ordering, and topological surface states. They possess various polytypes, often of similar formation energy, which can be accessed by selective synthesis approaches. They excel in mechanical, optical, and chemical sensing applications, and feature long-term air and moisture stability. In this Minireview, we summarize the recent progress in the field of noble-metal chalcogenides and phosphochalcogenides and highlight the structural complexity and its impact on applications.

1. Introduction

Noble-metal chalcogenides (NMCs) have been known since the 19th Century.[1,2] In contrast, their dichalcogenide forms (NMCs: MX₂, M = Pd, Pt, X = S, Se, Te) were well-characterized only in the 20th Century by the groups of Grønvold[3–7] and Hulliger.[8,9] Many NMDCs, for example, PtS₂ and PdTe₂,[10] and also some of the less-well-known noble-metal phosphochalcogenides (NMPCs),[11–14] are layered materials. However, interest in these has been limited because of their high cost, and little research has been carried out since the 1960s. This changed, however, with the “rediscovery” of NMDCs in 2014[15] as two-dimensional (2D) materials, since only one or few layers are required for application in 2D devices, thus removing the economic bottleneck and boosting research efforts in the field.

NMDCs gained a lot of attention as new members of the 2D family, since they showed a layer-controllable metal-to-semiconductor transition,[16,17] with few layers and the bulk phase featuring the topological properties of Dirac type-II semimetals.[18–21] The NMDCs also showed an outstanding performance as sensors, for example, for pressure or for specific molecular species.[22–26] Their chemistry, which includes highly anisotropic structural features,[23] low-energy differences between different polymorphs,[24] controllable phase changes,[25,32] and catalytic properties,[17,33–36] differs from that of the transition-metalloc dichalcogenides (TMDCs), such as MoS₂ and WSe₂.[37] This is caused by electron correlation and relativistic effects, which render their theoretical investigation challenging. To allow for direct comparison, this Minireview contains a recalculation of the structural, vibronic, and electronic features of these materials on the basis of density-functional theory (DFT; see the Supporting Information for details). This allows a consistent comparison between theory and experiment, in particular for phase stabilities and vibrational spectra. We provide an extensive characterization of NMDCs and NMPCs, highlighting recent developments in the field. A detailed review focusing on the application of NMDCs was recently published by Pi et al.[38] and an in-depth analysis of mechanical and photocatalytic properties of NMDC monolayers was reported by Xiong et al.[39] Here, we put an emphasis on the phase stabilities and structural prototypes, stabilities, and phase relationships.

PdX₂ favors the CdI₂-type structure, which is common to Group 4, and is referred to as the 1H phase (Figure 1b).[4,36,41] For TMDCs of Groups 5 and 6, the stability of the MoS₂ type (called the 2H phase, Figure 1c) is higher, which can be related to the increasing number of d electrons.[42–44] For TMDCs with larger numbers of d electrons, the 2H phase is typically unstable.[43]

For PtX₂, we determine the 2H phase to be unstable, whereas for PtSe₂, we obtain a large energy difference of 144 kJ mol⁻¹ (all energies are given per formula unit) to the 1T phase. Nonetheless, 2H-PtSe₂ has been observed experimentally in few-layer nanosheets by Wang et al.[50] and Lin et al.[29] have shown a controllable process to obtain mixed 1T-2H-PtSe₂ structures. These findings indicate that nanoscale processes can be used to access these high-energy structures.

In contrast, we predict much smaller energy differences of less than 58 kJ mol⁻¹ between the different polymorphs of PdX₂ (Table 1). In recent publications, these relatively small differences have led to some controversy in the prediction of the most stable phase when there are only a few layers.[15,26,46,63] Experimentally, PdTe₂ also prefers the 1T phase,[46,64] whereas both PdS₂ and PdSe₂ adopt a completely...
different layered structure with an orthorhombic unit cell, here called the 2O phase (Figure 1 a).[3,5,8,45,52] This structure is quite surprising as a result of its unique pentagonal tilings.[46] Whereas the 2H and 1T prototypes, as well as their differently stacked (3R) and distorted variants (1T' , T' AuTe2)[31,44] are similar to each other, the 2O structure seems to be special.

To provide insight into the stability and properties of these phases, we show that the structure of PdS2 and PdSe2 (Figure 1 a) is related to the pyrite-type structure (Figure 1 c).[3] We then connect the pyrite structure to its high-pressure phases (marcasite[50] and verbeckite[53] in Figure 1 d,f) and show its transformation back to the 1T phase (Figure 1 b).

In the next step, we turn to even more chemically complex systems, namely those containing substitutions and defects. We show similarities between the 2O phase and the structure of PdPS (Figure 1 h), which occurs as an intermediate to the PdP2 structure (Figures 1 i).

2.1. Relationship of the PdS2-Type and CdI2-Type

Simple concepts, such as oxidation state and charge distribution, help to identify the key factors for the structural stability of these polymorphs.[45] According to the ionic counting scheme, the metal centers in the octahedrally coordinated 1T phase formally have an oxidation state of +IV.[64] PtX2 with this oxidation state is stable due to the involvement of t orbitals, whereas PdX2 prefers to lower the oxidation state to +II. This can be achieved by pairing the chalcogen atoms to form (X2)n2− dimers, thereby leading to the pyrite- and marcasite-type structures, both with octahedral coordination of the metal centers (Figures 2 and 3 a). Phase transitions between the 1T, marcasite, and pyrite structures have been observed in IrTe2[80] and CoTe2[65]

We support the validity of these simple chemical descriptors with the Hirshfeld charge analysis (see Figure S1 in the Supporting Information). There, we show a large charge transfer (corresponding to a higher oxidation state) in the 1T structures of PdS2 and PdSe2 compared with a smaller charge transfer (corresponding to a lowered oxidation state) in the pyrite-like phases. For PdTe2, the charge transfer between the 1T and pyrite-phases has a similar magnitude, thus indicating no change in the oxidation state. Since formation of the Te-Te dimers is less likely, PdTe2 prefers the 1T phase.

The ground-state structure of PdS2 and PdSe2 has a lower symmetry than the pyrite prototype to avoid the d8 electron configuration in the octahedral crystal field. Therefore, one axis is elongated, imposing a change to a square-planar coordination. This leads to a novel structure with AB-stacked, buckled layers, which can be expressed by the sum formula Pd2(X2)n2−. Furthermore, one lattice vector (either a or b) is slightly elongated to avoid degenerate d states on the metal centers. Consequently, the PdS2-type structures are generally semiconductors,[3] but close their band gaps under pressure.[44,31,52]

2.2. High-Energy Structures

Under pressure, the PdS2-type structure reversibly transforms to the pyrite-type structure.[45,50,53,66] The pyrite-phase competes with the marcasite-type structure, as it is close in energy (ΔE = 6.2 kJ mol−1 for PdSe2). This is well-known for these two phases, since they differ mainly in the orientation of the chalcogen dimers (Figure 3 b).[66] Larchev and Popova[50] observed the marcasite phase of PdSe2 at 7.5 GPa and below 900°C, whereas the pyrite-phase was preferred above this temperature.

Other phases with reduced interlayer distances can occur between these phases.[66] In the case of PdS2, much higher pressures (> 16 GPa) are needed to obtain the pyrite phase.[49] Pyrite-PdS2 becomes superconducting at a critical temperature of 8 K at 37.4 GPa,[49] while pyrite-PdSe2 requires 13.1 K and 23 GPa.[52]

So far, the synthesis of PdTe2 in the pyrite phase has not been reported. Under a pressure of 5 GPa at 300°C, Soulard et al.[64] observed a continuous phase transition, where the interlayer Te–Te bond distances become shorter than the intralayer Pd–Te bond distances. This indicates that Te-Te dimers could be formed at elevated temperatures and pressures and may lead to pyrite-PdTe2.
To date, there are also no reports on the synthesis of PdS$_2$ or PdSe$_2$ in the 1T phase. The structural element that decides whether the 1T phase is more stable than the 2o phase is the chalcogen dimers. The chalcogen states are also the dominant states just below the Fermi level, as confirmed by the atom-projected density of states (Figures S2–S4). Hence, we expect that laser irradiation or electrostatic doping, as shown for few-layer MoTe$_2$, would be promising approaches to induce a phase transformation. From their structural prototypes, we conclude that uniform pressure is unlikely to transform 2o-PdS$_2$/Se$_2$ into 1T-PdS$_2$/Se$_2$, because the latter have larger cell volumes.

An indirect approach to obtain 1T-PdSe$_2$ via a high-energy phase has been suggested by Lei et al. At a temperature of 1600 K and a pressure of 11.5 GPa, 2o-PdSe$_2$ undergoes a phase transition to the verbeekite structure (Figures 1f and 3c). Verbeekite-PdSe$_2$ was first found as a mineral and appears to be a stable polymorph of PdSe$_2$ ($\Delta E \approx 1.4 \text{ kJ mol}^{-1}$), which is closer to the structure of PdP$_2$ (Figure 1i). Lei et al. predict that verbeekite-PdSe$_2$ may transform under pressure to the slightly distorted 1T structure known as AuTe$_2$-type (Figure 3c) and few-layer 1T-PdSe$_2$ may then be cleaved from this phase.

2.3. Ternary Metal Chalcogenides, Phosphides, and Beyond

In addition to pressure and temperature, substitution and defects also lead to unique structural motifs of the palladium chalcogenides. Hulliger showed that the ternary mixture PdSSe remains in the PdS$_2$-type, whereas PdSeTe already occurs in the CdI$_2$-type. These mixtures are layered structures that are an intermediate between the PdP$_2$ and PdS$_2$ structures. These mixtures...
Table 1: Chemical formula, structure prototype and relative stability, lattice parameters, band gaps, reported synthesis, and selected properties and applications of layered NM(D/P)Cs. Entries marked with an asterisk (*) refer to theoretical predictions from this work or from the given citation.

feature the PbS_{2}-type stacking, but have additional covalent interlayer P–P bonds (Figure 2).

Lastly, introducing chalcogen vacancies in PbSe_{2} is interesting for phase transformations and resistive-switching memory devices, because such defects have low diffusion barriers.[80] Many selenium vacancies can lead to an “inter-layer fusion”, as shown by Lin et al.[80] The resulting material has a new layered crystal structure, with the sum formula Pb_{1.5}Se_{3}, which could be an interesting component in hetero-junctions.[71] In PtTe_{2}, removing half of the chalcogen atoms to obtain PtTe yields a different layered structure with metallic monolayers.[81]
3. Synthesis

The first synthetic approaches to obtain bulk NM(D/P)Cs required reactions at high temperatures over the course of several weeks.\cite{3-5,51} The synthesis methods for NM(D/P)C materials have been strongly improved in recent years, when these materials regained scientific interest as a consequence of their layered bulk forms. Thin layers of these materials can be accessed by alternative synthesis approaches, such as chemical vapor deposition (CVD) or molecular beam epitaxy (MBE).

In 2015, PtSe$_2$ monolayers were successfully grown as high-quality, single-crystalline films by Wang et al.,\cite{17} who showed that a low growth temperature of 270°C was needed to directly selenize a Pt(111) surface. As a result of the necessary ultrahigh vacuum and a difficult transferring process, Dong and co-workers\cite{30} proposed an alternative method: CVD based on H$_2$PtCl$_6$ and selenium precursors in the temperature range 300–900°C on a sapphire substrate. This approach results in PtSe$_2$ nanosheets, which are easier to transfer to a poly(methyl methacrylate) substrate. Both approaches can yield the metastable 2H-PtSe$_2$ form.\cite{29}

A more scalable approach was reported by Yim et al.,\cite{24} who employed thermally assisted conversion on a Si/SiO$_2$ substrate. This method is remarkable due to the low growth temperature of 400°C, which allows polycrystalline PtSe$_2$ films with nanometer-sized grains to be obtained in a fashion that is directly compatible with back-end-of-line semiconductor processing.

These approaches are, however, more difficult to apply to PtS$_2$ due to the competing nonlayered PtS phase.\cite{57,72} Monolayer PtS$_2$ has been obtained by mechanical exfoliation,\cite{73} which limits the flake size to small lateral dimensions. Xu et al.\cite{57} reported the growth of wafer-scale PtS$_2$ films, but controlling the surface morphology and thickness is more challenging because of the need to convert the PtS phase into PtS$_2$ by varying the sulfur vapor pressure during annealing.\cite{72} The same challenge occurs with PdS$_2$,\cite{5} which has a different structure and has not yet been exfoliated. Single-crystalline bulk PdS$_2$ can be obtained by chemical vapor transport.\cite{45}

In 2017, 9 nm thick films of 2O-PdSe$_2$ were successfully obtained by Chow et al.\cite{49} by a self-flux method at 850°C over the course of 50 h. Oyedele et al.\cite{48} used the same synthesis approach and managed to mechanically cleave monolayers from the as-grown material. In 2019, the controllable CVD growth of 2O-PdSe$_2$, ranging from 2 to 20 layers on gold foil, was reported by Jiang et al.\cite{27} Highly anisotropic ribbons were formed, as a result of the orthorhombic crystal structure.

Bulk materials of the tellurides have been synthesized,\cite{4,54,74} but few-layer PtTe$_2$ and PdTe$_2$ are difficult to obtain. Li et al.\cite{95} used MBE to grow PdTe$_2$ with various thicknesses down to four layers on bilayer graphene. Liu
et al.\cite{56} employed MBE on a SrTiO$_3$(001) surface to obtain PdTe$_2$ between 1 to 20 layers, but more scalable approaches still need to be developed.

In general, all of the layered NMDCs have exfoliation energies that allow for mechanical exfoliation ($E_{\text{exfl.}} < 1 \text{ J m}^{-2}$, Table 1). Some of them, for example, PdTe$_2$, are clearly much harder to exfoliate than, for example, graphene. We want to highlight the possibility of exfoliating the NMPCs (Table 1), which have not been exfoliated to date.

4. Properties and Applications

4.1. Platinum Dichalcogenides

4.1.1. Electronic Properties

The PtX$_2$ materials excel in optoelectronic applications and feature strongly layer-dependent properties. The bulk materials range from semiconducting for PtS$_2$ (band gap of 0.7 eV)\cite{8} to metallic for PtTe$_2$.\cite{8} Hulliger measured a band gap of PtSe$_2$ of 0.1 eV from its resistivity, while theoretical investigations predicted semimetallic behavior.\cite{15,75} In 2015, Wang et al.\cite{17} confirmed that the bulk material is semimetallic by angle-resolved photoemission spectroscopy (ARPES) measurements. The authors confirmed the predictions\cite{15} of a semimetal-to-semiconductor transition at the monolayer limit, with a band gap of about 1.2 eV. This fascinating effect was supported by Ciarrochi et al.\cite{16} and later-on Shi et al.\cite{34} determined this transition to already happen at three layers. These observations agree with our calculations of the band structure (Figures S5–S9). Additionally, our calculations show a semimetal-to-semiconductor transition from bilayer to monolayer PtTe$_2$, with a significant influence of spin–orbit coupling (SOC) on the band structure.

Besides through the number of layers, the electronic properties of PtSe$_2$ can be tuned through strain and defect engineering. Whereas defect-free PtSe$_2$ is diamagnetic, a transition to a half-metallic ferromagnetic state for monolayer PtSe$_2$ at a critical strain of 5% was predicted,\cite{78} which favors the formation of single Pt vacancies and may cause the p-type
conductance in PtSe₂. These point defects occur intrinsically in ultrathin 1T-PtSe₂ layers,[77] and Aysar et al.[78] verified the emergence of magnetism as a result of vacancies in ultrathin metallic PtSe₂ both experimentally and theoretically. In addition, the authors showed that the layer number determines whether the ground-state ordering is ferromagnetic or antiferromagnetic. The possibility to engineer the magnetic properties of PtSe₂ through defects renders it very interesting for spintronics.

Lastly, exotic new electronic states can be realized in this family of materials by making use of SOC. Huang et al.[19] predicted that the P3̅m1 symmetry enables the existence of stable, strongly tilted type-II Dirac fermions in 1T-PtSe₂, which have been experimentally verified in 1T-PtTe₂.[98] These features might be the cause of the anomalous magnetotransport in PtSe₂ microflakes,[79] but require further investigation in the context of defect- and strain-induced magnetism.

### 4.1.2. Applications

The layer-sensitivity of the electronic properties is intriguing for nanoelectronic and sensing applications. Bulk PtS₂ and PtSe₂ feature p-type transport with Seebeck coefficients of 500 μV K⁻¹ and 40 μV K⁻¹, respectively.[8] A few-layer PtS₂ field-effect transistor (FET) shows mobilities exceeding 62.5 cm² V⁻¹ s⁻¹[80] and a few-layer PtSe₂-FET featured even higher room-temperature mobilities of 210 cm² V⁻¹ s⁻¹.[81]

Yim et al.[24] built a chemical gas sensor for NO₂ adsorption with ultrafast response times and high sensitivity: After selenizing 0.5 nm Pt by thermally assisted conversion, which led to thicknesses between 3 and 5 layers[82] the sensor responded to a 100 sccm flow of a NO₂/N₂ gas mixture for 10 s, with the original resistance being fully recovered in a pure N₂ flow at room temperature. The authors determined response and recovery times of 2.0 to 53.7 s and 7.4 to 38.7 s, respectively, at 0.1–1.0 ppm NO₂, with a limit of detection below 100 ppb. The superior gas-sensing properties of monolayer PtSe₂ have been theoretically verified by Sajjad et al.[22] hence, controlling the thickness of the PtSe₂ films down to the monolayer limit may improve the performance of the sensor. PtS₂ features even lower detection limits of 0.4 ppb for NO₂, but with a lower sensitivity and higher response/recovery times.[87]

Based on 4 nm thick PtSe₂ films, Yim et al.[24] built PtSe₂/n-Si Schottky diodes with a maximum responsivity of 490 mA W⁻¹ at a wavelength of 920 nm. The photoresponsivity of PtSe₂ in the infrared region allows its usage as an absorber with tunable sensitivity.[89] The mid-infrared sensitivity is very promising for optoelectronics and could be enhanced by defect-engineering[89] and the small band gap of 0.21 eV in a bilayer PtSe₂ combined with fast carrier dynamics could be exploited for saturable absorbers to generate ultrafast laser pulses.[89] Zeng et al.[88] reported PtSe₂/GaAs heterojunction photodetectors with peak sensitivity between 650 and 810 nm, where the on/off response speed of 5.5/6.5 μs is the highest among other Group 10 TMDCs. The performance of PtS₂ on Al₂O₃/Si substrates as a photodetector is lower (300 AW at 830 nm),[80] but PtS₂ on h-BN reaches 1560 AW⁻¹ at 500 nm.[80] The striking advantage of PtS₂ and PtSe₂-based photodetectors is their much lower response/recovery times compared, for example, to MoS₂ (4 s/9 s).[87]

The large response of the electronic properties of PtSe₂ to strain can be exploited for optical and mechanical sensors.[88] Du et al.[89] showed that a compressive strain of 3% induces a semiconductor-to-semimetal transition in a monolayer PtSe₂, which is easier to achieve than in MoS₂ because of the low in-plane stiffness of 64 N m⁻¹.

Few-layer PtSe₂ is semimetallic and the density of states at the Fermi level increases under strain, thereby giving rise to a large piezoresistive effect. This allowed Wagner et al.[92] to construct highly sensitive pressure sensors based on 4.5 nm thick PtSe₂ membranes. The sensitivity of these devices was an order of magnitude higher (5.51 × 10⁻⁴ mbar⁻¹) than those of other nanomaterial-based devices, including graphene, with a negative gauge factor up to −84.8. Boland et al.[90] advanced that approach by growing the PtSe₂ layers directly on top of flexible polyimide foils suitable for high-frequency applications. By patterning the PtSe₂/polyimide membranes in a three-dimensional kirigami fashion, Okogbue et al.[91] built FETs with device stretchability above 2000% as well as tunable electrical conductance and photoresponsivity.

In terms of catalysis, Chia et al.[90] determined that the catalytic activity of platinum dichalcogenides for the hydrogen evolution reaction (HER) increases with the size of the chalcogen atoms. PtTe₂ outperforms PtTe₃ as a result of the lower overpotential barrier of 0.54 eV versus the reversible hydrogen electrode (RHE) and also because it is less prone to tellurium stripping.[90] The performance of the bulk material towards the HER is reasonable, but can be enhanced by increasing the amount of edge sites[92] or by reducing the bulk thickness. Shi et al.[93] indicated atomically thin 1T-PtSe₂ to be a perfect electrocatalyst, with a record high HER efficiency comparable to the traditional Pt catalysts.

### 4.2. Palladium Ditelluride

#### 4.2.1. Characterization

For PtX₂, Raman spectroscopy has been shown to be a powerful method to monitor the layer thickness.[41] For PtTe₂, we predict a sizeable shift of about 50 cm⁻¹ of the E₈ mode in going from the bulk phase to a monolayer (Figure S10). Li et al.[90] reported the growth of four-layer PtTe₂ by molecular beam epitaxy, and measured the Raman spectrum for six layers, which showed a shift in the E₈ mode by about 7 cm⁻¹ to higher wavenumbers, whereas the A₁₈g mode remained unchanged.

As a consequence of the in-plane conductivity of PtTe₂, we largely overestimate the intensity of the in-plane E₈ mode relative to the out-of-plane A₁₈g mode. Prediction of the Raman spectra of metallic systems is challenging and will require further investigations. For comparison with experiments, we indicate the position of the out-of-plane A₁₈g mode in gray (Figure S10). Our calculated bulk frequencies are in excellent agreement with the experiments of Fei et al.[19] hence, we expect valid predictions for fewer layers. In this case, the influence of layer-layer coupling may lead to the appearance of new modes which are lower in symmetry than...
4.2.2. Electronic Properties

PdTe₂ is more similar to PtX₂ than to the other palladium dichalcogenides. Bulk 1T-PdTe₂ is metallic and diamagnetic and was predicted to undergo a transition to a narrow-gap semiconductor (about 0.14 eV) as a monolayer, whereas our calculations suggest a semimetallic state when SOC is included (Figures S11 and S12). Weak, temperature-independent paramagnetism ($\mu_{\text{eff}} = \mu_B$) is usually observed which might be caused by defects. PdTe₂ features rather strong interlayer interactions, but with a cleavage energy of 0.85 J m⁻², it should still be exfoliable (Table 1). These interlayer interactions mean it can be considered an intermediate between 2D and 3D materials. This intermediate state can lead to exotic electronic features, such as spin-polarized topological surface states, as a result of band inversion and complex spin textures.

The physics resulting from the intriguing electronic and phononic structure of PdTe₂ are still under debate. PdTe₂ gained a lot of attention as it was the first material featuring an interlayer interaction that is its own antiparticle. Majoranas can be realized as quasi-particles in condensed matter physics and are an important component for the realization of quantum information technology. Experimental realization of Majoranas has been reported only recently.

PdTe₂ becomes superconducting at temperatures below 2 K. The symmetry of the states causing the superconductivity is still under debate: although there is agreement that it is conventional superconductivity, it remains unclear whether it is of type-II or type-I. Even though the electronic structure of PdTe₂ changes greatly with the number of layers, the superconducting state remains robust even down to two layers and the superconducting surface states are robust under pressures up to 2.5 GPa.

Evidence of topological surface states in PdTe₂ was found by Liu et al. through ARPES measurements, but the Dirac point was found at the Γ-point deep below the Fermi level (−1.75 eV). Noh et al. found another Dirac cone much closer to the Fermi level (−0.5 eV) at $k = (0, 0, \pm 0.4)$ which features strong tilting in the $k_z$ direction. Thus, these are type-II Dirac semimetals, where the momentum-dependent tilting breaks Lorentz invariance. Only type-II Dirac semimetals allow for Majorana modes, type-I Dirac semimetals do not. Under pressures of 4.7–6.1 GPa, the Dirac cone can be tuned from type-II to type-I.

Another property of Dirac semimetals is the possibility to break either time reversal symmetry or inversion symmetry, and thus split the doubly degenerate Dirac cone into two separate Weyl nodes. These feature spin-polarized Fermi arcs as topological surface states, as well as an anisotropic negative magnetoresistivity. Since this intrinsic magnetism could be introduced by defects, PdTe₂ is an excellent candidate to study Weyl metals and superconductivity at the same time.

4.3. Palladium Disulfide and Diselenide

4.3.1. Characterization

The unique structural motif of crystalline 2O-PdS₂ and 2O-PdSe₂ allows the number of layers to be precisely determined by Raman spectroscopy, since stacks with an odd number of layers have $P_2_1/c$ symmetry with (inversion center), whereas stacks with an even number of layers have $Pca_2_1$ symmetry (no inversion center). Hence, the second harmonic generation occurs only in stacks with an even layer number. Furthermore, the Raman intensities are highly polarization-sensitive due to the anisotropic crystal structure.

For polycrystalline samples, extracting the number of layers from the Raman spectrum is more difficult because the layer-dependent wavenumber shifts are small. We predicted the spectra of monolayer, bilayer, and bulk 2O-PdX₂ (Figures 4b as well as Figures S13–S16), where our calculated frequencies are in good agreement with the experimentally observed ones.

In the case of 2O-PdSe₂, the $B_3$ mode increases its splitting to the $A_1$ mode for fewer layers, which can be employed for monitoring the exfoliation progress. We label the modes according to Oyedele et al. to facilitate comparison to experiments, where the label does not necessarily reflect the symmetry in the case of fewer layers. In the case of 2O-PdS₂, our calculations show an increase in the intensity of the $A_2^g/B_1^u$ signals relative to the $B_2^g/A_1^u$ signals, in excellent agreement with experiments.

We complement this section with the Raman and IR spectra of the potential 1T-PdS₂ and 1T-PdSe₂ (Figures S15 and S16). However, differentiating them from the 2O phase in experiment could be challenging: We predict the bulk 1T-$E_g$ mode to appear close to the bulk 20-$B_{1g}/A_1^u$ signals and the bulk 1T-$A_{1g}$ signal to be close to the bulk 2O-$A_2^g$ signal. Hence, if the 1T phase occurs only as a minor side phase, it is likely to be overlooked. An indication of the presence of the 1T phase could be the large intensity of the 1T bulk $A_1$ signal, especially for the semiconducting 1T-PdS₂. Whereas the $A_2^g$ and $B_{1g}$ signals of the 2O bulk usually have small intensities, a strong signal close to the $A_1$ mode could indicate the 1T phase. Furthermore, for fewer layers, the 1T-$E_g$ mode shifts significantly, whereas the 2O modes do not.

4.3.2. Electronic Properties

Bulk 2O-PdS₂ is a semiconductor with an indirect band gap of about 0.7 eV. We predict an increase of about 1 eV when going from the bulk phase to a monolayer. Wang et al. calculated a band gap of 1.6 eV for the monolayer, as well as an anisotropic in-plane stiffness of 58 N m⁻¹ in the $x$ direction and 82 N m⁻¹ in the $y$ direction, and large hole mobilities up to 339 cm² V⁻¹ s⁻¹.
In the case of PdSe$_2$ in the 2$O$ phase, there has been some recent controversy regarding the band gap of the bulk material$^{[48,110,111]}$. Hulliger$^{[8]}$ determined a small band gap of 0.4 eV through resistivity measurements. Several theoretical studies predicted a (semi)metal-to-semiconductor transition for bulk 2$O$-PdSe$_2$ as a result of the underestimation of the

Figure 4. Calculated Raman spectra and band structures for monolayer (ML), bilayer (BL), and bulk polymorphs of some exemplary layered NM(D/P)Cs.

In the case of PdSe$_2$ in the 2$O$ phase, there has been some recent controversy regarding the band gap of the bulk material$^{[48,110,111]}$. Hulliger$^{[8]}$ determined a small band gap of 0.4 eV through resistivity measurements. Several theoretical studies predicted a (semi)metal-to-semiconductor transition for bulk 2$O$-PdSe$_2$ as a result of the underestimation of the
band gap with the PBE functional.\textsuperscript{[46,110,112]} This led to misinterpretations of optical absorbance spectra yielding a zero band gap for bulk PdSe\textsubscript{2}.\textsuperscript{[46,46]} However, Chow et al.\textsuperscript{[49]} clearly proved 9 nm thick 20-PdSe\textsubscript{2} to be a semiconductor by integrating it into a FET and showing that the band gap could be closed by an external electric field. Zhang et al.\textsuperscript{[47]} measured a band gap of 0.5 eV for bulk PdSe\textsubscript{2}. Li et al.\textsuperscript{[113]} measured a bilayer band gap in the range of 1.15–1.35 eV, with the gap depending on the growth substrate as a result of the proximity screening effect.\textsuperscript{[114]} In monolayers, a band gap of 1.37 eV was measured.\textsuperscript{[47]} This is in line with our hybrid functional calculations, where we predict an increase in the band gap from 0.96 eV for the bulk phase to 1.8 eV for the bilayer and to 2.3 eV for the monolayer (Figure 4c and Figures S17 and S18).

Although neither 2O-PdS\textsubscript{2} nor 2O-PdSe\textsubscript{2} undergo metal-to-semiconductor transition, this has been predicted for the corresponding 1T phase.\textsuperscript{[15,46]} We calculate a band gap of 0.54 eV and 1.7 eV for bulk phase and monolayer 1T-PdSe\textsubscript{2}, respectively, and a semimetal-to-semiconductor transition in 1T-PdSe\textsubscript{2} with a monolayer band gap of 0.89 eV (Figures S17 and S18). These band gaps are about 0.5 eV larger than the ones calculated with PBE.\textsuperscript{[13]} Such a metal-to-semiconductor transition could be employed in single-material logical junctions with strongly suppressed Schottky barriers.\textsuperscript{[46]}

4.3.3. Applications

Both 2O-PdS\textsubscript{2} and 2O-PdSe\textsubscript{2} feature desirable properties for thermoelectric applications and transistors: Hulliger\textsuperscript{[48]} measured Seebeck coefficients of 240 and 500 μV K\textsuperscript{−1} for bulk 2O-PdS\textsubscript{2} and 2O-PdSe\textsubscript{2}, respectively. Chow et al.\textsuperscript{[49]} obtained a large total mobility of about 216 cm\textsuperscript{2} V\textsuperscript{−1} s\textsuperscript{−1} in 2O-PdSe\textsubscript{2}-based FETs after annealing, with an on/off ratio of 10\textsuperscript{4}. A key advantage of these materials is their air and moisture stability, even as monolayers.\textsuperscript{[46]} Very recently, bilayer PdSe\textsubscript{2} has also been grown by Jiang et al. through CVD.\textsuperscript{[27]}

The optical properties of PdSe\textsubscript{2} render it highly advantageous for sensing applications and photocatalysts.\textsuperscript{[39]} Long et al.\textsuperscript{[25]} reported a highly sensitive, air-stable, long-wavelength infrared photodetector based on a MoSe\textsubscript{2}/PdSe\textsubscript{2} heterojunction, which has a high photoresponsivity of 42.1 A W\textsuperscript{−1} at 10.6 μm. The specific detectivity (D*) of this device is as high as 8.21 × 10\textsuperscript{8} Jones, which is an order of magnitude higher than platinum diselenide (ca. 7 × 10\textsuperscript{8} Jones)\textsuperscript{[46]} and graphene (ca. 8 × 10\textsuperscript{9} Jones).\textsuperscript{[115]}

At shorter wavelengths of 780 nm, Zeng et al.\textsuperscript{[111]} obtained a photoresponsivity of 300.2 mA W\textsuperscript{−1} with a PdSe\textsubscript{2}-based photodetector decorated with black phosphorus quantum dots, with low rise and fall times of 38 and 44 μs, respectively. Wu et al.\textsuperscript{[50]} built a graphene/PdSe\textsubscript{2}/germanium heterojunction with a high polarization sensitivity for near-infrared imaging (0.2 to 3.04 μm) with a responsivity of 691 mA W\textsuperscript{−1} and rise/fall times of 6.4/92.5 μs. Walsmeier et al.\textsuperscript{[116]} built phototransistors with rise/fall times of about 156/163 μs, which are more than two orders of magnitude faster than other noble-metal dichalcogenide based phototransistors.

4.4. Noble Metal Phosphochalcogenides

The NMPCs have not yet been studied as 2D materials and with this Minireview we want to encourage more research in this direction. Similar to the 2O phases,\textsuperscript{[39]} the NMPCs can be expected to be interesting for photocatalytic applications. Jing et al.\textsuperscript{[160]} predict few-layer PdPX to absorb in the visible range and to have matching band edges for the water splitting reaction. This was confirmed by Jiao et al.,\textsuperscript{[117]} and also extended to the layered Pd(PS\textsubscript{2}).\textsuperscript{[118]} The band structures of a single layer of PdPX are more complicated as it consists of two sheets similar to the 2O structure, which are connected by an inversion center and P–P bonds (Figure 4c, Figures S19 and S20). The direct and indirect band gap transitions lie very close in energy, with bulk PdPS being an indirect-gap semiconductor and bulk PdPSe\textsubscript{2} a direct-gap semiconductor. As a consequence of the higher structural complexity, they feature many more visible Raman modes (Figure 4b, Figure S21, and Table S1).
