Air pollution and COVID-19 mortality in the United States: Strengths and limitations of an ecological regression analysis

X. Wu†, R. C. Nethery†, M. B. Sabath†, D. Braun†, F. Dominici†

Assessing whether long-term exposure to air pollution increases the severity of COVID-19 health outcomes, including death, is an important public health objective. Limitations in COVID-19 data availability and quality remain obstacles to conducting conclusive studies on this topic. At present, publicly available COVID-19 outcome data for representative populations are available only as area-level counts. Therefore, studies of long-term exposure to air pollution and COVID-19 outcomes using these data must use an ecological regression analysis, which precludes controlling for individual-level COVID-19 risk factors. We describe these challenges in the context of one of the first preliminary investigations of this question in the United States, where we found that higher historical PM$_{2.5}$ exposures are positively associated with higher county-level COVID-19 mortality rates after accounting for many area-level confounders. Motivated by this study, we lay the groundwork for future research on this important topic, describe the challenges, and outline promising directions and opportunities.

INTRODUCTION

The suddenness and global scope of the coronavirus disease 2019 (COVID-19) pandemic have raised urgent questions that require coordinated investigation to slow the disease’s devastation. A critically important public health objective is to identify key modifiable environmental factors that may contribute to the severity of health outcomes [e.g., intensive care unit (ICU) hospitalization and death] among individuals with COVID-19. Numerous scientific studies reviewed by the U.S. Environmental Protection Agency (EPA) have linked fine particles (PM$_{2.5}$; particles with diameter, $\leq$ 2.5 $\mu$m) to a variety of adverse health events (1) including death (2). It has been hypothesized that because long-term exposure to PM$_{2.5}$ adversely affects the respiratory and cardiovascular systems and increases mortality risk (3–5), it may also exacerbate the severity of COVID-19 symptoms and worsen the prognosis of this disease (6).

Epidemiological studies to estimate the association between long-term exposure to air pollution and COVID-19 hospitalization and death is a rapidly expanding area of research that is attracting attention around the world. Two studies have been published using data from European countries (7, 8), and many more are available as preprints. However, because of the unprecedented nature of the pandemic, researchers face serious challenges when conducting these studies. One key challenge is that, to our knowledge, individual-level data on COVID-19 health outcomes for large, representative populations are not publicly available or accessible to the scientific community. Therefore, the only way to generate preliminary evidence on the link between PM$_{2.5}$ and COVID-19 severity and outcomes using these aggregate data is to use an ecological regression analysis. With this study design, publicly available area-level COVID-19 mortality rates are regressed against area-level air pollution concentrations while accounting for area-level potential confounding factors. Here, we discuss the strengths and limitations of conducting ecological regression analyses of air pollution and COVID-19 health outcomes and describe additional challenges related to evolving data quality, statistical modeling, and control of measured and unmeasured confounding, paving the way for future research on this topic. We discuss these challenges and illustrate them in the context of a specific study, in which we investigated the impact of long-term PM$_{2.5}$ exposure on COVID-19 mortality rates in 3089 counties in the United States, covering 98% of the population.

Illustration of an ecological regression analysis of historical exposure to PM$_{2.5}$ and COVID-19 mortality rate

We begin by describing how to conduct an ecological regression analysis in this setting. COVID-19 death counts (a total of 116,747 deaths) were obtained from the Johns Hopkins University Coronavirus Resource Center and were cumulative up to 18 June 2020. We used data from 3089 counties, of which 1244 (40.3%) had reported zero COVID-19 deaths at the time of our analysis. Daily PM$_{2.5}$ concentrations were estimated across the United States on a 0.01° × 0.01° grid for the period 2000–2016 using well-validated atmospheric chemistry and machine learning models (9). We used zonal statistics to aggregate PM$_{2.5}$ concentration estimates to the county level and then averaged across the period 2000–2016 to perform health outcome analyses. Figure 1 illustrates the spatial variation in 2000–2016 average (hereafter referred to as “long-term average”) PM$_{2.5}$ concentrations and COVID-19 mortality rates (per 1 million population) by county.

We fit a negative binomial mixed model using COVID-19 mortality rates as the outcome and long-term average PM$_{2.5}$ as the exposure of interest, adjusting for 20 county-level covariates. We conducted more than 80 sensitivity analyses to assess the robustness of the findings to various modeling assumptions. We found that an increase of 1 µg/m$^3$ in the long-term average PM$_{2.5}$ is associated with a statistically significant 11% (95% CI, 6 to 17%) increase in the county’s COVID-19 mortality rate (see Table 1); this association continues to be stable as more data accumulate (fig. S3). We also found that population density, days since the first COVID-19 case was reported, median household income, percent of owner-occupied housing, percent of the adult population with less than high school

education, age distribution, and percent of Black residents are important predictors of the COVID-19 mortality rate in the model. We found a 49% (95% CI, 38 and 61%) increase in COVID-19 mortality rate associated with a 1-SD (per 14.1%) increase in percent Black residents of the county. Details on the data sources, statistical methods, and analyses are summarized in the Supplementary Materials. All data sources used in the analyses, along with fully reproducible code, are publicly available at https://github.com/wxwx1993/PM_COVID.

**Strengths and limitations of an ecological regression analysis**

Ecological regression analysis provides a simple and cost-effective approach for studying potential associations between historical exposure to air pollution and increased vulnerability to COVID-19 in large representative populations, as illustrated in our study in the previous section. This approach is regularly applied in many areas of research (10). Using our study as an example, we summarize in Table 2 the strengths, limitations, and opportunities considering (i) study design, (ii) COVID-19 health outcome data, (iii) historical exposure to air pollution, and (iv) measured and unmeasured confounders, with the goal of paving the way for future research.

Among the key limitations, by design, ecological regression analyses are unable to adjust for individual-level risk factors (e.g., age, race, and smoking status); when individual-level data are unavailable, this approach leaves us unable to make conclusions regarding individual-level associations. In the context of COVID-19 health outcomes, this is a severe limitation, as individual-level risk factors are known to affect COVID-19 health outcomes. It is important to note that confusion between ecological associations and individual associations may present an ecological fallacy. In extreme

Fig. 1. National maps of historical PM$_{2.5}$ concentrations and COVID-19 deaths. Maps show (A) county-level 17-year long-term average of PM$_{2.5}$ concentrations (2000–2016) in the United States in $\mu$g/m$^3$ and (B) county-level number of COVID-19 deaths per 1 million population in the United States up to and including 18 June 2020.
cases, this fallacy can lead to associations detected in ecological regression that do not exist or are in the opposite direction of true associations at the individual level. However, ecological regression analyses still allow us to make conclusions at the area level, which can be useful for policy-making (11). For the association between COVID-19 health outcomes and PM$_{2.5}$ exposure, we argue that area-level conclusions are valuable, as they can inform important immediate policy actions that will benefit public health, such as (i) prioritization of precautionary measures [e.g., personal protective equipment (PPE) allocations and hospital beds] to areas with historical higher air pollution and (ii) further strengthening the scientific argument for lowering the U.S. National Ambient Air Quality Standards for PM$_{2.5}$ and other pollutants. To completely avoid potential ecological bias, a representative sample of individual-level data is necessary. While this may not be feasible in the near future, as some COVID-19 outcome data become available at the individual level, existing approaches that augment county-level data with individual-level data (12) could be used to correct for ecological bias.

Furthermore, air pollution exposure misclassification, due to between-area mobility and within-area variation, is another potential source of bias that could affect the ecological regression results described in our example study. Methods to account for the propagation of exposure error into the ecological regression model (13) could be applied to help mitigate the impact of measurement error. Outcome misclassification is another limitation that can be partially overcome by accessing nationwide registry data with the validated cause of death (14). As in all observational studies, adjustment for measured and unmeasured confounding presents another key challenge in ecological regression analyses, which may be exacerbated when dealing with dynamic pandemic data, as in our study. Conducting studies using both traditional regressions and methods for causal inference as in Wu et al. (2) is necessary to assess the robustness of the findings.

Increasing the scientific rigor of research in this area requires access to representative, individual-level data on COVID-19 health outcomes, including information about patients’ residential address, demographics, and individual-level confounders. This is an enormous challenge that will require consideration of many privacy, legal, and ethical trade-offs (14). Future areas of research also include the application of statistical methods to quantify and correct for ecological bias and measurement error, reproducible methods for causal inference, and sensitivity analysis of measured and unmeasured confounding bias as suggested above. These strengths and limitations are illustrated further in the context of our own study (see the Supplementary Materials).

### DISCUSSION

Ecological regression analyses are crucial to stimulate innovations in a rapidly evolving area of research. Ongoing research has already focused on overcoming some aspects of these limitations (8, 15). For example, ecological regression analysis of air pollution and COVID-19, using data with finer geographic resolution, is being conducted for different countries and regions around the world. Cole et al. (8) published an ecological regression analysis using data in Dutch municipalities and found results consistent with our own investigation; the California Air Resources Board (CARB) is planning to conduct a similar study at the census tract level (15). Although an ecological regression analysis cannot provide insight into the mechanisms underlying the relationship between PM$_{2.5}$ exposure and COVID-19 mortality, studies are starting to shed light on the potential biological mechanisms that may explain the relationship between air pollution and viral infection outcomes (16). For example, it has been hypothesized that chronic exposure to PM$_{2.5}$ causes alveolar angiotensin-converting enzyme 2 (ACE-2) receptor overexpression and impairs host defenses (17). This could cause a more severe form

| Table 1. Mortality rate ratios (MRR), 95% confidence intervals (CI), and $P$ values for all variables in the main analysis. Details of the statistical models are available in section S2. Q, quintile. |
|---------------------------------|-----------------|----------------|
| MRR                            | 95% CI          | $P$ value |

Table 2. Strengths and limitations of ecological regression analyses applied to research on air pollution and COVID-19 and opportunities for future research.

| Study design: ecological regression | Strengths | Limitations | Future research |
|-----------------------------------|-----------|-------------|-----------------|
|                                   | Feasible, timely, and cost-effective | Cannot be used to make inference about individual-level associations, doing so leads to ecological fallacy | Augment county-level data with individual-level data to adjust for ecological bias (12) |
| Data are representative of the entire U.S. population | Cannot adjust for individual-level risk factors such as age, gender, and race (19–21) | Conduct studies of individual-level health records using traditional regression and causal inference methods as in Wu et al. (2) |
| Allows inference at the area level, which can be useful for policy-making (11) | Results are sensitive to the assumptions of the statistical model (11) | |
| Computationally efficient and can be conducted daily to allow for the dynamic nature of the data and observe temporal trends; see fig. S3 | Facilitates comparison of results across countries | |

| Outcome: COVID-19 deaths aggregated at the county level | Strengths | Limitations | Future research |
|--------------------------------------------------------|-----------|-------------|-----------------|
| Publicly available data updated almost daily | Potential for outcome misclassification (22), particularly differential misclassification over time and space, which could bias results | Access to nationwide registry data with the validated cause of death (14) |
| Analyses using county excess deaths as the outcome (23) | Individual-level data on COVID-19 deaths with geocoded addresses to link to air pollution data at the place of residence | |

| Exposure: 2000–2016 average exposure to PM$_{2.5}$ at the county level | Strengths | Limitations | Future research |
|------------------------------------------------------------------|-----------|-------------|-----------------|
| Use of well-validated atmospheric chemistry models and machine learning models (9, 24) | Aggregation assumes that everyone in a county experiences the same exposures, leading to exposure misclassification, especially for the largest counties | Individual-level data on COVID-19 deaths with geocoded addresses to link to air pollution data at the place of residence |
| PM$_{2.5}$ exposure estimated at fine grids, which can be aggregated to the county level to assess exposure even in unmonitored areas (24) | Can be used to assess historical exposures to air pollution but not real-time exposures | Additional statistical methods to account for the propagation of exposure error into the ecological regression model (13) |
| As opposed to using monitor data, aggregation of modeled estimates ensures that county PM$_{2.5}$ exposure estimates represent the distribution across the entire area | | |

| Measured confounders | Strengths | Limitations | Future research |
|---------------------|-----------|-------------|-----------------|
| More than 20 area-level variables capture age distribution, race distribution, socioeconomic status, population density, behavioral risk factors, epidemic stage, and stay-at-home orders (see tables S1 and S2) | County average features may not represent the features of COVID-19 patients, leading to inadequate adjustment | Causal inference approaches to adjust for measured confounding bias, producing results that are less sensitive to statistical modeling assumptions |
| These overlap with the confounder sets used in much of the previous literature on air pollution and health (25, 26) | Difficult to formalize the notion of “epidemic stage,” which may be an important confounder | |
| | | Causal inference approaches to assess covariate balance (2) |

| Unmeasured confounders | Strengths | Limitations | Future research |
|-----------------------|-----------|-------------|-----------------|
| Leverage existing approaches, such as the calculation of the E-value (27), to assess how strong the effect of an unmeasured confounder would need to be to explain away the associations detected (see section S3) | The most important threat to the validity of any observational study | Natural experiment designs and instrumental variables can be used to reduce the threat of unmeasured confounding but are less common |
| Even measures like the E-value cannot inform us about the likelihood that a strong unmeasured confounder exists; this must be evaluated on the basis of subject matter knowledge | | |

Wu et al., Sci. Adv. 2020; 6 : eabd4049  4 November 2020
of COVID-19 in ACE-2–depleted lungs, increasing the likelihood of poor outcomes, including death (18).

The associations detected in ecological regression analyses provide strong justification for follow-up investigations as more and higher-quality COVID-19 data become available. Such studies would include validation of our findings with other data sources and study types, as well as investigations into mediating factors and effect modifiers, biological mechanisms, impacts of PM$_{2.5}$ exposure timing, and relationships between PM$_{2.5}$ and other COVID-19 outcomes such as hospitalization. Research on how modifiable factors may exacerbate COVID-19 symptoms and increase mortality risk is essential to guide policies and behaviors to minimize fatality related to the pandemic. Such research could also provide a strong scientific argument for revision of the U.S. Ambient Air Quality Standards for PM$_{2.5}$ and other environmental policies in the midst of a pandemic.

The research described in this article was conducted under contract to the HEI, an organization jointly funded by the EPA (Assistance Award No. R-83467701), and certain motor vehicle and engine manufacturers. The contents of this article do not necessarily reflect the views of HEI or its sponsors, nor do they necessarily reflect the views and policies of the EPA or motor vehicle and engine manufacturers. Author contributions: X.W. and R.C.N. contributed equally to the paper. X.W. and R.C.N. contributed to formulation of the idea, data preparation, data analysis, data interpretation, and writing of the manuscript. M.B.S. and D.B. contributed to data preparation, data interpretation, and review of the manuscript. F.D. contributed to formulation of the idea, study design, data interpretation, funding, and writing of the manuscript. All authors contributed to the interpretation of the results and critical revision of the manuscript for important intellectual content and approved the final version of the manuscript. The corresponding author attests that all listed authors meet authorship criteria and that no others meeting the criteria have been omitted. F.D. is the guarantor. Competing interests: The authors declare that they have no competing interests. Data and materials availability: All data needed to evaluate the conclusions in the paper are present in the paper and/or the Supplementary Materials. Data and code are publicly available at https://github.com/wxwx1993/PM_COVID. Additional data related to this paper may be requested from the authors.
