Draft version July 26, 2018

ABSTRACT

We present a search for eclipses of $\sim$1700 white dwarfs in the Pan-STARRS1 medium-deep fields. Candidate eclipse events are selected by identifying low outliers in over 4.3 million light curve measurements. We find no short-duration eclipses consistent with being caused by a planetary size companion. This large dataset enables us to place strong constraints on the close-in planet occurrence rates around white dwarfs for planets as small as $2 R_{\odot}$. Our results indicate that gas giant planets orbiting just outside the Roche limit are rare, occurring around less than 0.5% of white dwarfs. Habitable-zone super-Earths and hot super-Earths are less abundant than similar classes of planets around main-sequence stars. These constraints give important insight into the fate of the large population of exoplanets orbiting main sequence stars.

INTRODUCTION

Searches for planets outside our solar system have focused primarily on hydrogen-burning main-sequence stars similar to our Sun (e.g., Bakos et al. 2004; Howard et al. 2010; Borucki et al. 2010). As we discovered that planets are nearly ubiquitous in our Solar neighborhood (Howard et al. 2010) and in the Kepler field (Petigura et al. 2013) searches around M-dwarfs gained popularity (e.g., Nutzman & Charbonneau 2008). Studies of M dwarfs enjoy a boost in sensitivity to small planets because transits block a larger fraction of the stellar disk and induce a larger amplitude reflex motion of the star around the barycenter due to their low mass. Some studies have also searched for and explored the planet occurrence rates as a function of stellar mass from M-dwarfs to intermediate-mass subgiants (Johnson et al. 2007). Microlensing campaigns survey stars of many types and are sensitive to planets around all massive hosts regardless of their stage in stellar evolution (Gaudi 2012) but followup characterization of these planets is impossible. However, there have been few dedicated searches for planets around white dwarfs (WDs).

Many studies including Mullally (2007), Farihi et al. (2008), and Klic et al. (2009) searched for infrared-excess indicative of planetary companions to WDs. They detected several brown dwarf companions (Zuckerman & Becklin 1992; Farihi et al. 2005; Steele et al. 2009) but no planetary-mass objects (Mullally 2007) also searched for companions using pulsations of WDs to look for periodic deviations in the pulse arrival times caused by an orbiting companion. They find evidence of a 2.4 M J companion in a 4.6 year orbit. Hogan et al. (2009), and Debès et al. (2005) conducted high contrast imaging surveys of nearly WDs to search for low-mass companions at large separations. Burleigh et al. (2006) found a brown dwarf in the near-IR spectrum of WD 0137-349 with an orbital period of only 2 hours. This object may have survived the common-envelope phase or migrated from larger orbital distances after the formation of the WD. Paedel et al. (2011) conduct a transit search for a sample of 174 WDs using SuperWASP data (Pollacco et al. 2006) and find no eclipsing companions but can put only weak constraints on the planet occurrence rates due to their small sample size (<10% for Jupiter-size planets). Drake et al. (2010) search for eclipses of $\sim$12,000 color-selected WDs using Catalina Sky Survey photometry and Sloan Digital Sky Survey spectroscopy. They find 20 eclipsing systems and three of them have radii consistent with substellar objects and no detectable flux in the spectra.

WDs have radii only $\sim$1% of the Sun, or about the same size as the Earth. This implies that an Earth-sized object transiting the WD with an impact parameter of 1.0 would cause a complete occultation. Although these occultations are short-duration, they can be easily detected from small ground-based telescopes with short exposure times and relatively low photometric precision (Drake et al. 2010). In addition, the most common WDs are old and cool with surface temperatures of $\sim$5000 K. Their small radii and low surface temperatures imply that their luminosity is low, with typical values of $\sim$10$^{-4}$ $L_{\odot}$, and the habitable zone is close-in ($a$ < $0.01$ AU, Agol 2011) giving rise to significant transit probabilities. This makes Earth-size planets orbiting in the habitable zones of old, cool WDs relatively easy to detect via the transit method.

Most main-sequence stars, including our Sun, will eventually end their lives slowly cooling as WDs. Since approximately 50% of main sequence stars host at least one planet (Mayor et al. 2011) it is interesting to consider their fate as the star evolves into a WD. It is unlikely that any planets inside $\sim$1 AU would survive engulfment by their host stars as they expand onto the red giant branch but it is unclear what becomes of the planetary debris. Since WDs quietly cool for the age of the universe, it is conceivable that new planets could form out of the debris of a previous generation of planets. Migration of planets from outside of 1 AU is also plausible, but little theoretical work has been done on the formation or migration of planets hosted by WDs. Several studies have identified pollution by heavy elements on the surfaces of WDs (Zuckerman et al. 2010) and IR excesses...
indicate a debris disk (Debes et al. 2011). Extensive work has been done to identify the chemical composition of this pollution. Silicates and glasses were detected in the atmosphere of six WDs by Jura et al. (2009) and interpreted as signs of accretion of asteroid-like bodies onto the WD. A detailed study by Xu et al. (2014) using data from the Keck and Hubble Space Telescopes showed strong evidence that the composition of metals in the atmospheres of WDs G29-38 and GD 133 closely mirror the composition of the bulk Earth. Furthering the idea that close-in terrestrial planets orbit and eventually accrete onto WDs.

We present a systematic search for eclipses of WDs by planetary-size objects in the Pan-STARRS1 medium-deep fields (Tonry et al. 2012). We use a combination of astrometric and photometric selection techniques to identify 3179 WDs with a range of ages and temperatures. Each WD was observed on 1000-3000 epochs during the past 5 years for a total of 4.3 million measurements. Although we do not detect any substellar companions, this large number of observations allows us to place tight constraints on the occurrence rates of planets orbiting WDs.

2. METHODS

2.1. WD sample

We analyze a total of 3179 WD candidates spread across the 10 medium-deep fields spanning 70 square degrees on the sky. Each field is observed on 1000-3000 epochs with four to eight consecutive 240 s exposures per night. Our sample of WDs is segregated into two categories. We identify 661 targets using their proper motions as described in (Tonry et al. 2012) (astrometric sample hereafter). These objects have a high probability of being bona fide WDs and a very low contamination rate.

The remaining 2518 WDs were selected based on their photometric colors (color-selected sample hereafter). We use the following criteria to select the locus of hot, blue stars from the ($\text{g}_P - \text{r}_P$) vs. ($\text{r}_P - \text{i}_P$) color plane shown in Figure 2. ($\text{g}_P - \text{r}_P < 0.18 + 1.4(\text{r}_P - \text{i}_P)$, ($\text{g}_P - \text{r}_P > 0.06 + 1.4(\text{r}_P - \text{i}_P)$, ($\text{g}_P - \text{r}_P < 0.25 - 1.25(\text{r}_P - \text{i}_P)$, and $\text{i}_P < 22$. This sample is restricted to hot WDs due to the requirement of blue colors and is likely contaminated by other hot stars.

To quantify the contamination rate of the color-selected sample we created a Besançon galactic simulation of the medium-deep fields (Robin et al. 2003). When we make the same color-cuts we find that 42% of the stars are bona fide WDs according to the model. The stars that are within this locus but not WDs are mostly distant A and B-type subdwarfs in the halo of the galaxy. Closer F-type subdwarfs would also fall into the locus, but are mostly too bright to be included in our sample. We also find that the contamination rate is highly dependent on apparent magnitude with the fainter stars being much more likely to be WDs. We assume a 58% contamination rate for our color-selected sample for all further analysis. This reduces our total number of WDs to 1718.

2.2. Control sample

Our control sample consists of stars with similar magnitudes and colors to the astrometrically-selected WDs but with undetectable proper motions. These should be relatively hot stars with radii much larger than WDs around which we would not expect to see the very short-duration eclipses indicative of a planet occulting a WD. We can compare the number of potential eclipses found in the WD sample to the number that we find in the control sample to better understand the frequency of eclipse-like events caused by non-astrophysical effects.

We select the control sample by binning the astrometric sample of WDs in 2-dimensional color bins of $\text{r}_P$ vs. ($\text{r}_P - \text{i}_P$). For each bin that contains at least one WD we select two times the number of WDs in that bin from a sample of all stellar detections derived from deep stacks of the medium-deep fields excluding stars that are already part of the WD samples. Figure 4 shows our control sample and astrometric WD sample in the $\text{r}_P$ vs. ($\text{r}_P - \text{i}_P$) color plane. If fewer than three field stars are available in a particular bin we select all available stars. This produces a total of 1296 stars for the control sample which is later trimmed down to 1288 by removing RR-Lyrae, Delta-Scuti and other variable stars (see § 2.4).

2.3. Light curves

Light curves are extracted for each WD and control sample star by directly analyzing the first-level Pan-STARRS1 photometry product (SMF files). These SMF files consist of the raw photometry extracted from the calibrated images before a zero-point or precise world coordinate system (WCS) is established. Each camera exposure corresponds to a single SMF file. For each SMF file we first find the WCS solution in order to associate pixel locations with sky positions. We then associate the per-image detections with detections in deep stacks of the medium-deep fields excluding stars that are already part of the WD samples. The resulting magnitudes for all detections within 5 arcminutes of the target are also extracted and recorded along with the target instrumental magnitudes. All epochs for which a target could not be matched to a detection in the SMF file are carefully
recorded and the neighboring star photometry is still extracted if available. This ensures that we are sensitive to large decreases in flux that may cause the target to fall below the detection threshold in a particular image and in some cases we can use the photometric statistics of the neighboring stars to explain the non-detection. We also record the pixel locations relative to the entire CCD array and particular chip for each epoch.

2.4. Eclipse detection

Since eclipses are rare and extremely short duration traditional periodic search algorithms such as the box-least-squares periodogram (BLS, Kovács et al. 2002) fail to recover such signals. BLS excels at detecting signals in the regime of many transits with low single-event S/N but planetary eclipses of our target stars would produce very infrequent, but very deep, high S/N eclipses. Instead we employ an extremely simple eclipse detection technique. We look for low outliers in the light curves (dropouts) that are caused either by a complete non-detection or show a deficit of flux relative to the median flux level ($\Delta F$) that is greater than five times the measurement uncertainty ($\Delta F/\sigma_\Delta F \geq 5$). Figure 3 shows the distribution of $\Delta F$ and $\Delta F/\sigma_\Delta F$ for all light curves.

The raw light curves are heavily contaminated with non-detections and large flux drops that could be indicative of an eclipse event or a variety of non-astrophysical scenarios. For every dropout we first check that the star did not fall off of, or too near the edge of a chip. We initially noticed that the dropout events were concentrated around the edges of the chips. This is likely caused by the PSF fit failing due to a strong gradient in the background region near the edges of the chips. This effect is worse at the corners of the chips near the readout electronics. For these reasons we remove all light curve measurements that fall within 10 pixels ($2^\prime 5$) of an edge or within 100 pixels ($25^\prime$) of a corner. We consider this filter unbiased with respect to eclipses because there is no reason to expect that real eclipses would preferentially occur when the stars fall near the edge of a chip. Measurements with reported positions that fall between chip gaps or off the array are also excluded at this stage. All non-detections are removed with these chip location-based filters.

If the photometry of the neighboring stars also show a large decrease in flux at the same time of the target dropout, clouds or poor seeing is likely to blame. We exclude all measurements for which the median magnitude of the neighboring stars drops by more than 0.5 magnitudes or the standard deviation of the neighbor magnitudes is greater than one. We also de-correlate the target relative flux measurements against the median $\Delta F$ of the neighboring stars to reduce the effect of spatially-dependent extinction.

Now that we have removed most of the egregious outliers from the light curve we re-define the measurement errors. We sum in quadrature the reported measurement uncertainties with the standard deviation of the light curve (by filter). Measurements with $\Delta F/\sigma_\Delta F \geq 5$ are considered eclipse candidates. As in the top panel, the solid blue line is the distribution for the WDs and the dashed red line comes from the control sample stars.

At this stage we use the VARTOOLS package to create BLS and analysis-of-variance (AoV) periodograms (Hartman et al. 2008; Kovács et al. 2002; Schwarzenberg-Czerny 1989; Devor 2005) for all WD and control sample stars. We visually inspect these periodograms and the light curves phase-folded to the ephemeris that corresponds to the highest peak in each periodogram. Obvious periodic variable stars are removed from further analysis. Thirty-three RR-Lyrae and Delta-Scuti stars, one dwarf nova (IY Uma) and three variables of unknown type are identified and removed at this stage.

For the remaining dropouts we check their CCD locations against the regions of the array that are consistently

---

Fig. 2.—The color-selected WDs (blue points) are identified by the narrow tail of extremely blue stars in the $(g_{\text{P1}}-r_{\text{P1}})$ vs. $(r_{\text{P1}}-i_{\text{P1}})$ color plane. The small black points are all detections from the deep stacks not selected for either the control or WD samples.

Fig. 3.—Top: Distribution of relative flux measurements for all WD and control sample stars. The solid blue line is the distribution for the WDs and the dashed red line is for the control sample stars. Bottom: Distribution of relative flux measurements divided by the measurement uncertainties corrected by adding in quadrature the reported measurement uncertainties with the standard deviation of the light curve (by filter). Measurements with $\Delta F/\sigma_\Delta F \geq 5$ are considered eclipse candidates. As in the top panel, the solid blue line is the distribution for the WDs and the dashed red line comes from the control sample stars.

Fig. 4.— Illustration of the filtering process for a light curve of a typical g’=18.9 WD in medium-deep field 3. The total number of measurements and the number of dropouts (\(\Delta F/\sigma_0 \geq 5\)) are shown in the lower-right of each panel. Dropout candidates are plotted as triangles. a) Raw light curve before any filtering. Error bars are equivalent to the reported measurement uncertainties. Notice the large number (1977) of dropout candidates. b) Light curve after applying the chip location-based filters described in 2.4. c) Light curve after removing measurements in which neighboring stars show large deviations from the median flux level or large scatter. d) Light curve after de-correlating against the neighboring star relative flux and re-scaling the measurement uncertainties by adding the reported uncertainties in quadrature with those of the neighboring stars. e) Light curve after the final level of photometry-based filtering. Two dropout events remain after all photometry-based filters. Postage stamp images are downloaded and visually inspected for the remaining dropout events.

masked by the Pan-STARRS1 Image Processing Pipeline (IPP). After applying all of the photometry-based tests we are left with 11570 potential dropout events and of a total of 4.3 million detections. 2570 of the dropout candidates are from the control sample and the remaining 9000 are from the merged WD samples. This photometric filtering process for a single representative case is illustrated in Figure 4 and the total number of detections and non-detections removed at each stage in the filtering process are listed in Table 1.

We download the corresponding postage stamp images for any dropouts that make it through all of these light curve-based tests for additional screening. In addition to the postage stamp corresponding to the dropout we also download a deep stack around the target and the image that corresponds to the light curve measurement that is closest to the median value for that filter. We apply a few more automated filters before visually inspecting the remaining candidates. The images are automatically inspected for masking or CCD defects around the target that produce not-a-number (nai) values, very poor seeing, or clouds as indicated by a low zeropoint magnitude. We also perform aperture photometry on the three images and correct to an absolute apparent magnitude using the zeropoint magnitude provided in the image headers. Our photometry acts as check that the magnitude value reported by the IPP is in rough agreement with simple aperture photometry.

As a final step we use the HOTPANTS implementation of the ISIS image subtraction software (Alard 2000) to produce a difference image using the deep stack as a template. We convolve the template to match the PSF and zero point of the dropout candidate image and subtract the convolved template from the candidate postage stamp. This difference image was used to aid the visual inspection of the 133 dropout events that could not be explained by any of the photometry or image-based filters. Figure 5 shows an example dropout candidate image and the image-differencing processes used for visual inspection. We find no eclipse with a duration compatible with an eclipse by a substellar object in any WD or control sample light curve.

3. ANALYSIS

3.1. Theoretical eclipse probabilities

In order to assess the likelihood that an occultation would have occurred during our observing window, we calculate the probability of eclipse as a function of eclipse depth and then apply the noise properties and eclipse detection techniques that we used in our search. This tells us the number of eclipses we should have been able to detect as a function planet radius, orbital semi-major axis and the occurrence rate of planets around WDs (\(\eta\)).

The flux when a dark sphere eclipses a uniformly illuminated sphere is given by Equation 1 (Mandel & Agol 2002). Where \(\kappa_1 = \cos^{-1}[(1 - p^2 + b^2)/2b]\), \(\kappa_0 = \cos^{-1}[(p^2 + b^2 - 1)/2pb]\), and \(p \equiv R_p/R_{WD}\) is the planet to white dwarf radius ratio.
Eclipses will only occur if $|b_0| < 1 + p$, therefore the probability that a randomly-oriented, circular orbit will eclipse is

$$P_{\text{eclipse}} = \frac{R_p + R_{\text{WD}}}{a}.$$  \hspace{1cm} (4)

Although systems with $|b_0| < 1 + p$ will eclipse at some time during the orbit, the fraction of orbital phase covered during eclipse is small. The probability that any part of an eclipse will overlap with the integration time of our survey is

$$P_{\text{phase}} = \frac{T_{\text{dur}} + E}{P},$$  \hspace{1cm} (5)

where $P$ is the orbital period and $T_{\text{dur}}$ is the eclipse duration and $E$ is the integration time.

For eclipses with durations shorter or equal to the exposure time the likelihood of any given measurement being in eclipse is then the sum of the probabilities for all possible orbital configurations that would produce an observed eclipse of depth $m$. For example, a measurement with $m = 0.1$ could be caused by a very small planet transiting slowly across the face of the star with a transit duration approximately equal to the exposure time. Alternatively, an eclipse of a much larger planet causing a complete occultation of the WD on a very short-period orbit would streak across the face of the star with a transit duration much shorter than the exposure time. The mean flux during the exposure may look identical in these two cases. Both of these cases and all other situations that could cause an observed eclipse depth $m$ must given the appropriate weight in the final likelihood calculation. Figure 6 shows the eclipse depth probability distributions for a few hypothetical scenarios.

By the definition of our eclipse detection algorithm each exposure is sensitive to eclipses of depth $m \geq 5\Delta F/\sigma_{lc}$. By integrating over all scenarios that would cause an observed eclipse depth greater than or equal to $5\Delta F/\sigma_{lc}$ for every measurement we derive the probability that we could have detected an eclipse during each exposure if $\eta = 1$. The inverse of the summed probabilities over all exposures for all light curves gives a total probability that we could have detected an eclipse during each exposure if $\eta = 1$. The inverse of the summed probabilities over all exposures for all light curves gives a total probability that we could have detected an eclipse during each exposure if $\eta = 1$. The inverse of the summed probabilities over all exposures for all light curves gives a total probability that we could have detected an eclipse during each exposure if $\eta = 1$. ### 3.2. Occurrence constraints

If we treat the number of expected eclipses as a Poisson expectation value ($\lambda$), the probability that we should detect $k$ eclipses is
Probability of measuring an eclipse with depth $\Delta F$ during a single 240 s exposure of a random WD that hosts a single companion with the orbital parameters shown, $p$ is the planet to star radius ratio, $R_p$ is the radius of the planet in Earth radii, $a/R_{WD}$ is the orbital semi-major axis scaled to the radius of the WD, and $a$ is the semi-major axis in AU. Right: Model eclipse light curves for the planet parameters shown on the left panel and an impact parameter 1.0. The red circle is the mean flux for an exposure centered on the mid-eclipse time. The bar extending from the red circle shows the length of the exposure time. This is the largest signal that we could expect to find for planets with these parameters. This corresponds to the maximum $< \Delta F >$ bin with a probability greater than zero in the left panel.

\[ P(k, a, p) = \frac{\lambda(a, p)^k \exp(-\lambda(a, p))}{k!}. \]  
\( k = \Delta F > 5 \)

\[ \eta \leq \frac{\ln (1 - C)}{\lambda_1(a, p)}, \]  
assuming the planet occurrence rate is constant as a function of $a$ and $p$.

4. DISCUSSION

Although we find no convincing detections of eclipses with durations consistent with substellar objects we are still able to put strong constraints on the WD-hosted planet occurrence rate. Figures 8 and 9 show the maximum occurrence rate that is consistent with our observations at 95% and 68% confidence levels assuming $R_{WD} = 0.01 R_{\odot}$ and $M_{WD} = 0.6 M_{\odot}$. This should be a relatively good approximation since the masses and radii of most WDs fall close to these values. For each reported occurrence rate ($\eta$) we first state the value corresponding to the maximum allowable occurrence rate averaged over the specified region of interest for the 95% confidence limit and then the 68% confidence limit immediately following in parenthesis. For example, our results suggest that less than 0.4% (0.2%) of WDs host planets with radii greater than ~2 Earth radii and semi-major axis between 0.002 and 0.01 AU. 0.4% is the maximum occurrence rate allowed by our data at 95% confidence and 0.2% is the same for a confidence level of 68%.

It is an interesting exercise to break up the two-dimensional occurrence limits into regions that correspond to classes of planets that we are more familiar with orbiting main-sequence stars. Other studies have shown similarities between the architectures of exoplanetary systems around low-mass M-dwarfs with the moons of Jupiter (Muirhead et al. 2012) and scaled-down versions of our solar system or exoplanetary systems around more massive stars. If we scale down the orbital distances
be approximated as

$$L_R \approx 2.44R_{WD} \left( \frac{\rho_{WD}}{\rho_p} \right)^{1/3}.$$  

(8)

For our assumed WD properties the Roche limit for a Jupiter-like planet is $L_R \approx 0.01$ AU. It is not surprising that we do not detect any Jupiter-sized objects inside 0.01 AU. However, we can equate a population of Jupiter-sized planets orbiting between 0.01 and 0.04 AU to the hot Jupiters observed orbiting very close to solar-type stars. In this regime an eclipse duration is slightly longer than the duration of a single exposure. Therefore our expectation value for eclipses is slightly overestimated, however we do not expect this to be the dominant source of error in the occurrence rate limits. The mean maximum occurrence rate for WD-hosted hot Jupiters ($R = 10 - 20R_\oplus$) is 0.5% (0.2%). Indicating that hot Jupiters around WDs are very rare or non-existent. This is in good agreement with the frequency of hot Jupiters around solar-type stars measured to be between 0.3% and 1.5% (Marcy et al. 2005; Gould et al. 2006; Cumming et al. 2008; Howard et al. 2011; Mayor et al. 2011; Wright et al. 2012).

A rigid body can orbit slightly closer to the WD without being tidally disrupted. Planets with radii larger than $\sim 1.5 R_\oplus$ generally have densities lower than that of the Earth and likely have an extended gas-dominated atmosphere (Weiss & Marcy 2014). However, some super-Earths with slightly larger radii have high densities consistent with a rocky composition, e.g., CoRoT-7b (Léger et al. 2009), Kepler-20b (Gautier et al. 2012), and Kepler-19b (Ballard et al. 2011). This class of planets may be the remaining cores of evaporated gas giant planets (Hébrard et al. 2004). Our results suggest that less than 1.5% (0.6%) of WDs host planets with radii between 2.0 and 5.0 $R_\oplus$ orbiting with semi-major axis between 0.005 and 0.01 AU. Howard et al. (2012) measure an occurrence rate of 13% for 2-4 $R_\oplus$ planets with orbital periods shorter than 50 days. However, the occurrence rate drops with shorter orbital periods to 2.5% for periods shorter than 10 days. Our lack of detections indicate that hot super-Earths are almost certainly less common around WDs than they are around solar-type stars.

Perhaps the most interesting planets to consider are those that have an equilibrium temperature such that they could sustain liquid water on their surfaces. Since WDs cool and decrease in luminosity as they age, the habitable zone (HZ) boundaries also change as a function of time. Agol (2011) define the WD continuous habitable zone (CHZ) as the range of semi-major axis that would be within the HZ for a minimum of 3 Gyr and also outside of the tidal destruction radius for an Earth-density planet. For a 0.6 $M_\odot$ WD this corresponds semi-major axis between 0.005 and 0.02 AU. Our data show that planets in the CHZ with radii between 2-5 $R_\oplus$ could be present around no more than 3.4% (1.3%) of WDs. This is significantly less than the predicted frequency of Earth-size planets in the habitable zone of solar-type stars ($\sim 22\%$, Petigura et al. 2013).

A large population of short-period planets orbiting solar-type and M-dwarf stars has been observed. We might expect WDs to host similar planets if they can reform from a post-giant phase debris disk or migrate from...
larger orbital distances once the star becomes a WD. However, our observations are quite sensitive to planets larger than the Earth orbiting close to the WD, and the lack of any eclipses suggests that these processes are highly inefficient if they occur at all. There are very few planets in short-period orbits around WDs.

4.1. Future survey design

Since eclipse times are generally shorter than the 4 min exposure times for the medium-deep survey we explore the idea of designing a similar survey with shorter exposure times and increased sensitivity to shallow eclipses. This would cause less dilution of the eclipse signals over the duration of the exposure. We re-calculate the expected eclipse rates for exposure times of 30, 60, and 120 seconds scaling the measured noise properties from our 240 s data. We use the mean eclipse rate for planets with radii between 1-5 $R_\oplus$ orbiting between 0.005 and 0.02 AU as a metric for comparison. Figure 10 illustrates the result. We find that decreasing the exposure time gives a modest boost in sensitivity to these planets for a given total survey exposure time. The most dramatic increase in sensitivity when going to short exposure times is for the very short period planets orbiting interior to 0.003 AU. However, planets are not able to withstand the tidal forces this close to the WD so we would not expect planets to exist in this regime. The expected eclipse rate in our region of interest is dominated by signal-to-noise of the individual detections. Although the eclipses are diluted by long exposure times, this is balanced by the increased gain in sensitivity to these shallow, diluted eclipses due to the greater signal to noise obtained in longer exposures. This suggests that the best way to detect these Earth to Neptune size planets in the WD CHZ may be to increase the etendue of the survey to detect more WDs on a greater number of epochs by covering a large area of the sky at high cadence. The ATLAS (Tonry 2011) and Large Synoptic Survey Telescope (Ivezic et al. 2008) surveys should be ideal for detecting these extremely rare events.

4.2. Pan-STARRS1 3π

The Pan-STARRS1 3π survey covers 30,000 square degrees with approximately 60 observational epochs per object (Kaiser et al. 2010 Magnier et al. 2013). The depth and cadence are inferior to that of the medium deep fields, but the huge amount of sky observed makes it interesting to explore the contribution that this survey could make to the occurrence rate limits if we were to perform a similar analysis on a combined dataset.

We start with an order-of-magnitude estimate of the number of WDs we would expect to find in the 3π survey data via reduced proper motion. The exposure times for the 3π survey are 60 seconds vs. 240 seconds for the medium deep fields, but let us assume that our ability to detect WDs is limited by the length of the observational baseline and not by signal to noise of the detections. Since the sky coverage is a factor of ~400 greater in the 3π survey it is reasonable to scale the number of astrometrically-selected WDs found in the medium deep fields (661) by 400. Therefore, we expect to find ~30,000 WDs via reduced proper motion in the 3π data. Since each WD is observed 60 times this gives a total of 1.8 million measurements. The shorter exposure times increase our sensitivity to very short duration eclipses, however the largest gain in sensitivity is to planets orbiting well inside the tidal destruction radius (see Figure 10 and [4]). Combining these 1.8 million epochs with the 4.3 million epochs from the medium-deep fields increases our total number of measurements by a factor of 1.4 and strengthens (decreases) our maximum occurrence constraints by this same factor. This ~ $\sqrt{2}$ improvement would not change our primary conclusion that planets around WDs are rare.

5. CONCLUSIONS

Our systematic search for eclipses of WDs in the Pan-STARRS1 medium-deep fields places strong constraints on the WD planet occurrence rates. We analyze a sample of ~3000 WDs selected via proper motion and color along with a control sample of ~1200 stars. These WDs were observed for 5 years on over 4.3 million epochs.
We search for potential eclipses by identifying low outliers in the light curves. A total of 133 candidate eclipses are identified after applying a series of photometry then image-based filters to remove outliers caused by weather, CCD artifacts, or an improperly modeled PSF. After visual inspection of all candidates we find none that is consistent with an eclipse or occultation by a substellar object.

We calculate the number of expected eclipses if every WD hosted at least one planet (\(\eta = 1\)) by convolving a trapezoidal transit model with the survey exposure time and integrating over all possible geometric orientations and many values of \(R_p\) and \(a\). The expected number of eclipses are treated as a Poisson expectation value for the rate of events which are converted into 95% (68%) confidence intervals. We then invert these rates to obtain the rate of events which are converted into 95% (68%) R and many values of and integrating over all possible geometric orientations WD hosted at least one planet (\(\eta\). The expected number of that is consistent with our data.

Our results suggest that hot Jupiters around WDs are at least as rare as they are around solar-type stars, occurring around no more than 0.5% (0.2%) of WDs. Hot super-Earths occur around no more than 1.5% (0.6%) of stars, and super-Earths in the CHZ are present around no more than 3.4% (1.3%) of WDs. All evidence presented in this study indicate that short-period planets around WDs are significantly less abundant than short-period planets orbiting main-sequence stars.

The Pan-STARRS1 Surveys (PS1) have been made possible through contributions of the Institute for Astronomy, the University of Hawaii, the Pan-STARRS Project Office, the Max-Planck Society and its participating institutes, the Max Planck Institute for Astronomy, Heidelberg and the Max Planck Institute for Extraterrestrial Physics, Garching, The Johns Hopkins University, Durham University, the University of Edinburgh, Queen’s University Belfast, the Harvard-Smithsonian Center for Astrophysics, the Las Cumbres Observatory Global Telescope Network Incorporated, the National Central University of Taiwan, the Space Telescope Science Institute, the National Aeronautics and Space Administration under Grant No. NNX08AR22G issued through the Planetary Science Division of the NASA Science Mission Directorate, the National Science Foundation under Grant No. AST-1238877, the University of Maryland, and Eotvos Lorand University (ELTE). Support for this work was provided by National Science Foundation grant AST-1009749. Finally, we would like to thank Prof. Andrew Gould for his critical review and extremely helpful suggestions that greatly enhanced the quality of this work.
