Origin and evolution of the deep thermochemical structure beneath Eurasia

N. Flament1,†, S. Williams1, R.D. Müller1, M. Gurnis2 & D.J. Bower3

A unique structure in the Earth’s lowermost mantle, the Perm Anomaly, was recently identified beneath Eurasia. It seismologically resembles the large low-shear velocity provinces (LLSVPs) under Africa and the Pacific, but is much smaller. This challenges the current understanding of the evolution of the plate-mantle system in which plumes rise from the edges of the two LLSVPs, spatially fixed in time. New models of mantle flow over the last 230 million years reproduce the present-day structure of the lower mantle, and show a Perm-like anomaly. The anomaly formed in isolation within a closed subduction network ~22,000 km in circumference prior to 150 million years ago before migrating ~1,500 km westward at an average rate of 1 cm year$^{-1}$, indicating a greater mobility of deep mantle structures than previously recognized. We hypothesize that the mobile Perm Anomaly could be linked to the Emeishan volcanics, in contrast to the previously proposed Siberian Traps.
The long-wavelength structure of Earth’s lowermost mantle is characterized by two large low-shear velocity provinces (LLSVPs) under Africa and the Pacific, ~15,000 km (Fig. 1a) in diameter and 500–1,000 km high\textsuperscript{1,2}. In addition, a single, spatially small (~<1,000 km in diameter, ~500 km high) deep mantle structure named the ‘Perm Anomaly’ was recently identified through seismic tomography\textsuperscript{3}. The discovery of the Perm Anomaly poses fundamental questions about its dynamic relationship with the much larger LLSVPs, its uniqueness, its age and the formation of lower mantle structures in general. The structure of the lower mantle is important for reconstructions of the plate–mantle system\textsuperscript{4–8} in deep geological time because the reconstructed locations of most large igneous provinces (LIPs) and kimberlites over the past 320 million years (Myr) correlate with the edges of present-day LLSVPs, leading to the concept of a plume generation zone at LLSVP boundaries\textsuperscript{9}. This concept has been used to build a model of absolute motion of tectonic plates over the Phanerozoic (past 540 Myr)\textsuperscript{10}, under the assumptions that LLSVPs are fixed\textsuperscript{11} and non-deforming\textsuperscript{10} through time. However, numerical models suggest that the influence of sinking slabs\textsuperscript{11,12} should result in LLSVP deformation and motion\textsuperscript{13–16} over hundreds of million years. Additionally, measurements of differential splitting of SKS and SKKS seismic phases reveal anisotropy along the boundary of the African LLSVP\textsuperscript{17} and along the eastern boundary of the Perm Anomaly\textsuperscript{18} suggesting deformation is occurring on the edges of these structures. Finally, while SKS phases passing along the edge of LLSVPs suggest gradients in shear velocity that are too large to be explained by thermal variations alone\textsuperscript{19,20}, how chemically distinct LLSVPs are from the rest of the mantle remains unclear\textsuperscript{21}. Previous studies have shown that the large-scale structure of the lower mantle results from past subduction history\textsuperscript{11–13,15,16,22–23}, without quantifying the geographic match between predicted and tomographic structures or the motion of individual thermochemical structures. Although some geodynamic model\textsuperscript{23,24} produce a Perm-like anomaly linked to the African LLSVP, its tectonic origin remains to be explained.

In this study, we report paleogeographically constrained forward global mantle flow models predicting a discrete structure similar in scale and geographical location to the recently discovered Perm Anomaly, and quantify the match between predicted and seismically inferred lower mantle structure across a series of mantle flow and tomography models. In the flow models, the Perm-like anomaly forms in isolation before 150 million years ago (Myr ago), within a long-lived, ~22,000 km-long, closed subduction network consisting of the Mongol-Okhotsk subduction zone to the west, northern Tethys subduction zone to the south, and east Asian subduction zone to the east. The models predict that the discrete Perm-like anomaly has coherently migrated westward at a rate of 1 cm year\textsuperscript{-1} over the last 150 Myr, which is incompatible with the hypothesis that lower mantle structures can be considered fixed and rigid over time. Because of its past mobility, the Perm Anomaly may not be linked to the Siberian Traps, but rather to the Emeishan volcanics.

Results

Predicted lowermost mantle temperature. We address the questions raised by the discovery of the Perm Anomaly through comparison of the lowermost mantle temperature predicted by forward global mantle flow models constrained by tectonic reconstructions\textsuperscript{25,26} (Methods) to tomography images. In dynamic models, slabs subducting deep into the mantle deform a basal layer, initially uniform, which is either thermal or thermochemical (Methods, Table 1). In the reference model (case 1, Table 1), predicted present-day temperature ~200 km above the core–mantle boundary (CMB) is characterized by two large high-temperature regions under Africa and the Pacific and one smaller, spatially distinct high-temperature region north-east of the African Anomaly, under eastern Europe and western Russia (Fig. 1b). For case 1, the predicted present-day CMB and surface heat flow are respectively 10.4 TW and 40.3 TW, which is consistent with constraints\textsuperscript{26}. The spatial extent of the large high-temperature regions is in first-order agreement with the position and shape of the African and Pacific LLSVPs in individual tomography models (for example, S40RTS (ref. 27), Fig. 1a) and in a vote map of tomography models\textsuperscript{12} (Fig. 1), and the predicted smaller structure under eastern Europe and western Russia matches the location of the Perm Anomaly in tomography (Fig. 1). Visual comparison suggests the reference model better fits the long-wavelength shape than similar models\textsuperscript{16}. The edges of the model LLSVPs tend to be hotter than their interior (Fig. 1), which is consistent with a plume generation zone\textsuperscript{9}.

Cluster analysis of mantle flow and tomography models. To make a more quantitative comparison between lower mantle temperature predicted by global geodynamic models with seismic velocity anomalies of selected tomography images, we use cluster analysis (Methods). Cluster analysis objectively classifies a set of points into groups of points with similar variations in a given property with depth. Following Lekic et al.\textsuperscript{23} we consider two clusters and depths between 1,000 and 2,800 km (Fig. 2). For S40RTS (ref. 27), the procedure reveals a low-velocity cluster below ~2,400 km depth, in which seismic velocity anomalies are reduced to ~0.9%, and a high-velocity cluster in which seismic velocity anomalies are increased to +0.4% (Fig. 2b). For case 1f, which was seismically filtered\textsuperscript{28} (Methods) for direct comparison to tomography, a low-velocity and high-velocity cluster are also distinct below ~2,400 km depth, although predicted anomalies are larger (down to ~1.2% and up to +0.6%, Fig. 2d). The geographic distribution of low-velocity clusters shows two large LLSVPs and a Perm-like anomaly in both S40RTS and case 1f (Fig. 2a,c), confirming that the extent and location of predicted deep mantle structures is compatible with seismic images. Given the small influence of seismic filtering, including on the extent and location of the Perm-like anomaly (Fig. 2c,e), we do not seismically filter other cases for which the clustering procedure reveals a high-temperature and low-temperature cluster below ~2,400 km depth (Fig. 2f).

Sensitivity of model success to parameters. We test the sensitivity to model parameters by considering 27 cases with varying Rayleigh number, initial model age, initial slab depth, viscosity, relative and absolute\textsuperscript{4,5,29} plate motions, and basin layer density (Table 1). To assess model success, we introduce a ‘Perm Score’ (PS) (Table 1) that visually characterizes model clusters; the method scores whether a predicted Perm-like anomaly is present and separate from the African LLSVP (PS = 2), present and linked to the African LLSVP (PS = 1), or absent (PS = 0). A Perm-like anomaly is present and separate from the African LLSVP in 15 out of 27 cases. Moreover, this Perm-like anomaly is the only isolated, small anomaly that forms in all of these 15 cases; consequently there must be a specific cause for the generation of this unique feature. The Perm-like anomaly is separate at present-day for initial model age >200 Myr ago, initial slab depth >800 km, and when absolute plate motions are based on hotspot tracks\textsuperscript{4,23} and paleomagnetic data\textsuperscript{3} as opposed to mapping slab remnants from seismic tomography\textsuperscript{7} (Table 1). These results confirm the influence of initial conditions and subduction history on model results\textsuperscript{12}, and we verified elsewhere\textsuperscript{23} that models initiated with LLSVPs in the initial
condition are consistent with the present-day mantle structure. No Perm-like anomaly is predicted when the Rayleigh number $Ra$ is ten times larger or 100 times smaller than in the reference case ($Ra = 7.8 \times 10^7$).

To assess model success beyond the prediction of a Perm-like anomaly, we calculate the accuracy with which the global geographic distribution of predicted model clusters reproduces that of tomography clusters. This accuracy, defined as the ratio of successfully predicted areas to total area (Methods, Fig. 3), is calculated for distinct mantle flow and tomography models, each of which is based on different assumptions and delivers non-unique inferences of the true pattern of mantle structure. The accuracy varies between 0.54 and 0.81 across 27 model cases and seven tomography models (Methods, Fig. 4a), and is above random (0.5) even for the least successful models. For each case, we report the average accuracy for all seven tomography models, which ranges between 0.56 and 0.76. Average accuracy decreases with decreasing initial model age, is $\leq 0.61$ when the initial model age is 100 Myr ago or younger and when $Ra$ is large ($7.8 \times 10^8$), and is between 0.61 and 0.71 when the basal layer is purely thermal or $< 2.54\%$ chemically denser than ambient mantle (Fig. 4a; Table 1). The average accuracy is $\geq 0.71$ for all other cases. The average accuracy for GyPSuM-S (ref. 30) (0.65) is lower than for other tomography models (between 0.69 and 0.75), which might reflect that GyPSuM-S (ref. 30) is an inversion for geodynamic and mineral physics constraints in addition to the seismic constraints used in other tomography models.

**Origin of the Perm Anomaly.** Having established that the present-day lower mantle structure is well reproduced by mantle flow, we investigate the dynamics leading to the formation of the Perm-like anomaly. The model high-temperature clusters (Fig. 2e,f) correspond to temperatures that are $\leq 10\%$ higher than ambient at 2,677 km depth (Fig. 1b). Following the evolution of temperature at 2,677 km depth in the reference case (Fig. 5a,c,e) reveals that despite its present-day proximity with the African LLSP, the incipient Perm-like anomaly formed $\sim 190$ Myr ago centred on 100°W/60°N (Fig. 5a), between three long-lived subduction systems: Mongol-Okhotsk along Eurasia

---

**Figure 1 | Lower mantle structure inferred from seismic tomography and predicted by a mantle flow model.** (a) Seismic velocity anomalies at 2,677 km depth for tomography model S40RTS (ref. 27). (b) Predicted present-day mantle temperature at 2,677 km depth for case 1. The solid gray contour indicates a value of five, and the dashed gray contour a value of one in a vote map for tomography models. Present-day coastlines are shown in black.
The Perm-like anomaly ceases when the Mongol-Okhotsk Ocean closes 150 Myr ago. The Perm-like anomaly then migrates ~1,500 km westward as pushed by descending slabs\textsuperscript{12,15,23} subducting under east Asia (Fig. 5c–f). The coherent translation of the discrete, Perm-like anomaly allows us to estimate an average motion rate of 2 cm year\textsuperscript{−1} over the last 150 Myr. This ongoing westward flow is compatible with SKS–SKKS splitting measurements revealing anisotropy with a fast east–west direction in the lowermost mantle under eastern Europe and western Russia\textsuperscript{16}, potentially due to lattice-preferred-orientation of post-perovskite\textsuperscript{24}. Moreover, the prediction is consistent with deformation on the eastern boundary of the Perm Anomaly and the presence of high seismic velocity structures to the east of the Perm Anomaly that also reveal anisotropy in SKS–SKKS splitting measurements\textsuperscript{18}. Together with seismic observations\textsuperscript{18} and previous models\textsuperscript{13–16}, our results challenge the long-term fixity and rigidity of deep-mantle thermochemical structures.

### Discussion

The genesis of the Perm-like anomaly within a long-lived, closed subduction network with a perimeter ~22,000 km (Fig. 5a) could explain why a single small LSV\textsuperscript{18} is observed seismically, and why only one isolated thermochemical pile forms in our models. Although the geometry and timing of past plate boundaries is increasingly uncertain back in geological times due to decreasing amounts of preserved ocean floor\textsuperscript{35}, this tectonic setting is unique for the last 230 Myr. We find that the Perm-like anomaly is only separate at present if slabs are inserted to depths > 800 km (PS 2 in Table 1) in the initial condition at 230 Myr ago. This suggests that the subduction network would have been established at the latest between ~330 and ~280 Myr ago, depending on slab sinking rates\textsuperscript{7}. For the reference case, the present-day Perm-like anomaly is chemically distinct (~550 km in thickness based on 50% dense material), high temperature (~850 km in thickness based on mantle 20% hotter than ambient) and may actively contribute to mantle upwelling (Fig. 5f). The predicted chemical anomaly is consistent with the ~500 km thickness of the Perm Anomaly inferred from seismic images\textsuperscript{3}, but the thermal anomaly may be underestimated in the model. In contrast to models in which the Perm-like anomaly is similar to LLSPVs (Fig. 2d), global seismic models have not reported shear-velocity anomalies in the Perm Anomaly that are as low as in the LLSPVs\textsuperscript{3} (Fig. 2b), although caution must be exercised as the amplitudes of seismic anomalies are often poorly constrained tomographically\textsuperscript{36}. One possibility to explain the apparent smaller shear-velocity reduction in the Perm Anomaly\textsuperscript{3} (Fig. 2b) is that it could be compositionally different from the LLSPVs: decreasing the density of the basal layer results in a better match of the Perm Anomaly, but a poorer global match (Figs 3 and 4; Table 1).

Our reconstructions of past mantle flow link the formation of the Perm Anomaly to the history of subduction around east and west, northern Tethys to the south, and east Asia to the east (Fig. 5a,b). In this tectonic scenario\textsuperscript{32,33}, subduction to the west of the Perm-like anomaly ceases when the Mongol-Okhotsk Ocean closes 150 Myr ago. The Perm-like anomaly then migrates ~1,500 km westward as pushed by descending slabs\textsuperscript{12,15,23} subducting under east Asia (Fig. 5c–f). The coherent translation of the discrete, Perm-like anomaly allows us to estimate an average motion rate of 1 cm year\textsuperscript{−1} over the last 150 Myr. This ongoing westward flow is compatible with SKS–SKKS splitting measurements revealing anisotropy with a fast east–west direction in the lowermost mantle under eastern Europe and western Russia\textsuperscript{16}, potentially due to lattice-preferred-orientation of post-perovskite\textsuperscript{24}. Moreover, the prediction is consistent with deformation on the eastern boundary of the Perm Anomaly and the presence of high seismic velocity structures to the east of the Perm Anomaly that also reveal anisotropy in SKS–SKKS splitting measurements\textsuperscript{18}. Together with seismic observations\textsuperscript{18} and previous models\textsuperscript{13–16}, our results challenge the long-term fixity and rigidity of deep-mantle thermochemical structures.
central Asia between 230 and 150 Myr ago. The formation of the Perm Anomaly would have occurred several tens of million years after this subduction network was established, as slabs slowly sank. The Perm Anomaly appears between 220 and 80 Myr ago depending on the Rayleigh number, the initial slab depth and the initial model age (Methods, Table 1). Although tectonic uncertainties increase back in geological time, some reconstructions suggest that a closed network of subduction zones 20,000 km in perimeter might have been established around the Mongol-Okhotsk Ocean 410 Myr ago37, in which case the Perm Anomaly might have existed for much of the Phanerozoic. Structures similar to the Perm Anomaly are likely to have existed earlier in Earth’s history, controlled by past subduction zone configurations.

Conceptual6 and geodynamic22,23,24 models suggest that plumes mostly rise from deep thermochemical structures to form LIPs at Earth’s surface. The reconstructed location of the ~258-Myr ago Emeishan LIP falls within the network formed by the Mongol-Okhotsk, northern Tethys, and East Asia subduction zones between 230 and 150 Myr ago33 (Fig. 5a). In contrast, the reconstructed location of the ~251 Myr ago Siberian Traps does not reconstruct within this subduction network between 230 and 150 Myr ago (the reconstructed location of the Siberian Traps is outside the region shown in Fig. 5a). Because the models show that the Perm anomaly originated within this subduction network, we propose that the Emeishan LIP is a possible product of the Perm Anomaly, in contrast to the Siberian Traps3,8. These competing hypotheses could be tested in future convection models including mantle plumes23, contrary to the models presented here, and based on tectonic reconstructions extending into the Paleozoic, but that do not assume that the Emeishan LIP originated from the Pacific LLSVP, contrary to existing reconstructions8,37.

Figure 2 | Clustering of lower mantle seismic tomography and predicted mantle temperature. (a) High-velocity (blue) and low-velocity (red) regions between 1,000 and 2,800 km depth for seismic tomography model S40RTS (ref. 27). (b) Seismic velocity profiles in high-velocity and low-velocity regions for S40RTS (ref. 27). The solid curves are the mean, and the transparent envelopes are the associated standard deviation, of the global low-velocity cluster (red), global high-velocity cluster (blue) and low-velocity cluster for the separate Perm-like anomaly (black). (c,e) Same as a but for seismically filtered28 case 1 (c) and case 1 (e). (d,f) Same as b but for seismically filtered28 case 1 (d) and case 1 (f). In a,c,e, the solid gray contour indicates a value of five and the dashed gray contour a value of one in a vote map for tomography models5. Present-day coastlines are shown in black.
Results are shown for case 1 and S40RTS (ref. 27) (tomography and blue (false negative) indicates low-temperature cluster for the model and low-velocity cluster for the tomography, green (false positive) indicates high-temperature cluster for the model and high-velocity cluster for the tomography and blue (false negative) indicates low-temperature cluster for the model and low-velocity cluster for the tomography. Present-day coastlines are shown in black. Results are shown for case 1 and S40RTS (ref. 27) (a,b), case 2 and S362ANI (ref. 38) (c,d), e,f, and case 5 and S362ANI (ref. 38) (e,f).

Figure 3 | Spatial match between predicted lower mantle structure and that inferred from seismic tomography. Orange (true positive) indicates high-temperature cluster for the model and low-velocity cluster for the tomography, gray (true negative) indicates low-temperature cluster for the model and high-velocity cluster for the tomography, green (false positive) indicates high-temperature cluster for the model and high-velocity cluster for the tomography and blue (false negative) indicates low-temperature cluster for the model and low-velocity cluster for the tomography. Present-day coastlines are shown in black. Results are shown for case 1 and S40RTS (ref. 27) (a,b), case 2 and S362ANI (ref. 38) (c,d), e,f, and case 5 and S362ANI (ref. 38) (e,f).

Methods

Paleogeographically constrained dynamic Earth models. We solve the equations for incompressible convection in a spherical domain with finite-elements using the code CitcomS\textsuperscript{39}, modified as described in ref. 25 to progressively assimilate the velocity of tectonic plates, the age of the ocean floor and the location and polarity of subduction zones determined in one million year intervals from global plate tectonic reconstructions\textsuperscript{32,33} with continuously closing plates\textsuperscript{40}. This semi-empirical approach ensures our computations represent Earth’s imposed tectonic history, allowing us to reconstruct the history of deep mantle flow over the last 230 Myr. This approach is guided by the current intractability of computing time-dependent models of Earth’s plate–mantle system with the resolution required to dynamically achieve tectonic-like features, including one-sided subduction\textsuperscript{41} and conserve the energy of the system simultaneously. Here we give a summary of the governing parameters and model setup that are further described in refs 23,42.

The vigour of convection is defined by the Rayleigh number $Ra = (\zeta_0 \rho_0 g_0 \Delta T_{01}) / (\kappa_0 \eta_0)$, where $\zeta_0 = 3 \times 10^{-12} \text{K}^{-1}$ is the coefficient of thermal expansion, $\rho_0 = 4,000 \text{kg m}^{-3}$ is the density, $g_0 = 9.81 \text{m s}^{-2}$ is the gravity acceleration, $\Delta T = 2,825 \text{K}$ is the temperature change across the mantle, $h_m = 2,867 \text{km}$ is the thickness of the mantle, $\kappa_0 = 1 \times 10^{-2} \text{m}^2 \text{s}^{-1}$ is the thermal diffusivity, $\eta_0 = 1 \times 10^{21} \text{Pa s}$ is the viscosity, and the subscript ‘0’ indicates reference values. With the values listed above, $Ra = 7.8 \times 10^8$. These values are varied between model cases such that $Ra$ varies between $7.8 \times 10^8$ and $7.8 \times 10^9$ (Table 1).

We approximate the Earth’s mantle as a Newtonian fluid in which viscosity varies with depth and temperature following $\eta = n_0(r) \exp\left\{\frac{E_0}{T - T_0} - \frac{E_1}{R(T + T_0)}\right\}$, where $n_0(r)$ is a pre-factor defined with respect to the reference viscosity $n_0$ for four layers: above 180 km, between 160 and 310 km depth, between 310 and 660 km depth and below 660 km depth, in the lower mantle. Values of $n_0(r)$ for each layer are given as comma-separated lists in Table 1, where ‘0–100’ indicates that the reference viscosity linearly increases with depth from 10 to 100 throughout the lower mantle, and 0/1/1 indicates that the reference viscosity of the asthenosphere is 0.1 under oceanic plates and 1 under continental plates. $E_0$ is the activation energy taken as 100 kJ mol$^{-1}$ in the upper mantle and 30 kJ mol$^{-1}$ in the lower mantle, $R = 8.31 \text{J mol}^{-1} \text{K}^{-1}$ is the universal gas constant, $T$ is the dimensional temperature, $T_g = 452 \text{K}$ is a temperature offset and $T_S = 1.685 \text{K}$ is the ambient mantle temperature. The activation energy and temperature offset are chosen to limit variations in viscosity to three orders of magnitude across the range of temperatures without imposing a yield stress. Such lateral viscosity contrasts are lower than expected to occur within the solid Earth\textsuperscript{41}, but they can be computed with a resolution that allows us to compute time-dependent mantle flow models. A phase change $F$ at 660 km depth, as described in Flamant et al.\textsuperscript{42} is considered in some model cases (Table 1).

For the initial condition and progressive data assimilation, the thickness and temperature of the lithosphere are derived using a half-space cooling model and the synthetic age of the ocean floor\textsuperscript{42}, and simplified tectono-thermal ages for the
Cluster analysis of lower mantle structure. We use cluster analysis to objectively classify a set of points on the surface into groups of points with similar variations in a given property with depth. For each flow model case (or tomography model), temperature (or seismic velocity) profiles are treated as 196,996 independent vectors of 31 coordinates specifying the temperatures (or seismic velocities) sampled at 31 depths between 1,000 and 2,800 km\(^3\), with an average resolution of 58 km. Each vector corresponds to equally-spaced locations on Earth’s surface (average distance ~0.45\(\deg\)). The vectors are grouped into two clusters using a k-means clustering\(^{32}\) procedure that keeps the variance in squared Euclidean distance between vectors small within each cluster. We use the scientific Python implementation of the k-means algorithm (http://docs.scipy.org/doc/scipy/reference/generated/scipy.cluster.vq.kmeans2.html). The average and standard deviation of temperature profiles for each cluster are shown in Fig. 2 for the reference case, along with the average and standard deviation of temperature profiles for the high-temperature cluster in the Perm region.

Seismic filtering. We seismically filter our reference case 1 following Ritsma et al.\(^{28}\) to verify if lower mantle features apparent in the model temperature field would be resolved by global tomography\(^{27}\). We consider that both temperature and composition variations cause variations in shear velocity. For the thermal contribution, we determine wave speed variations (\(dV_\text{S}\)) scaling departures from average temperature at each depth (\(dT\)) using \(dV_\text{S}/dT = -7.0 \times 10^{-4} \text{ km/s} \cdot \text{K}^{-1}\) (ref. 44). For the chemical contribution, we determine wave speed variations (\(dV_\text{S}\)) from variations in the composition field at each depth (dC) using \(dV_\text{S}/dC = 4 \times \delta \rho_{\text{basal}}\) (ref. 45), where \(\delta \rho_{\text{basal}}\) is the density of the chemically distinct basal layer. Thermal and compositional contributions to wave speed variations are jointly considered following \(dV_\text{S} = dV_\text{T} + dV_\text{C} = f_c \times dV_\text{S}/dC \times dC\), where \(f_c = 0.05\) is the contribution of composition to total wave speed anomalies.

Quantification of model success. We quantitatively how well the clusters obtained for each model case reproduce the global geographical distribution of clusters obtained for global S-wave tomography model\(^{22,30,36-49}\) by computing the accuracy

\[
\text{Acc} = (TP + TN) / A,
\]

where TP is the area of true positives, TN the area of true negatives and A the total area. Three examples of the spatial distribution of true positives, true negatives, false positives and false negatives with respect to tomography models are shown in Fig. 3. The accuracy is computed for each model case, both globally and in the region between 10°–80°E and 40°–75°N that includes the Perm Anomaly, against seven global S-wave tomography models (Fig. 4): SAW2B16 (ref. 46), HMSL-S (ref. 47), S362ANI (ref. 38), GyPSuM-S (ref. 30), S40RTS (ref. 27), Savani (ref. 48), SEMUCB-WM1 (ref. 49). Values of the global and regional accuracies averaged over the seven tomography models are reported in Table 1.

Age of the Perm-like anomaly. We report the age \(a_\text{Perm}\) from which the separate Perm-like anomaly is ~190 km thick (based on a mantle temperature 10% higher than ambient, and with model output every ~10 Myr) in Table 1.

Data availability. Maps of the geographic distribution of tomography and flow model clusters are available at https://www.earthbyte.org/origin-evolution-perm-anomaly/. The computer code that supports the findings of this study is available from the corresponding author upon reasonable request.

Figure 4 | Quantitative match between predicted lower mantle structure and seismic tomography models. Accuracy (true positive area plus true negative area over total area), with which the geographical distribution of clusters of mantle temperature between 1,000 and 2,800 km depth is shallower than ambient, and with model output every ~10 Myr.)
Figure 5 | Formation of the Perm Anomaly. Predicted mantle temperature, flow and composition for case 1 at 2,677 km depth (a,c,e) and along crosssections (green lines) at 60° latitude (b,d,f). Results are shown at 191 Myr ago (a,b), 111 Myr ago (c,d) and present-day (e,f). Reconstructed subduction locations are shown as red lines with triangles on the overriding plate, reconstructed mid-oceanic ridges and transform faults are shown as yellow lines, and reconstructed coastlines are shown in gray. The brown contours indicate 50% concentration of dense material. In a,c,e, the blue contours indicate subducing plates with temperature 10% lower than ambient mantle at 489 km depth. The green circle in a is the location of the ~258 Myr ago Emeishan LIP, reconstructed at 191 Myr ago.

Acknowledgements
This research was undertaken with the assistance of resources from the National Computational Infrastructure (NCI), which is supported by the Australian Government. N.F. and R.D.M. were supported by ARC IH130200012. S.W. was supported by SIEF RP 04-174. M.G. and D.J.B. were supported by Statoil ASA and by the NSF under grants CMMI-1028978, EAR-1161946 and EAR-1247022. Figures were constructed using the Generic Mapping Tools and matplotlib. We thank T.C.W. Landgrebe for advice in calculating accuracy and sensitivity, D. Steinberg for advice on cluster analysis, J. Ritsema for sharing the seismic filter for S40RTS, and three anonymous reviewers for comments that improved the quality of the manuscript.

Author contributions
N.F. ran and analysed the models, S.W. instigated the study and implemented the cluster analysis, R.D.M. and M.G. developed the concepts of the study and D.J.B., M.G. and N.F. developed the framework to assimilate tectonic reconstructions in CitcomS. All authors contributed to the writing of the manuscript, led by N.F.
