Approximation Schemes for Multiperiod Binary Knapsack Problems

Zuguang Gao, John R. Birge, and Varun Gupta

Abstract

An instance of the multiperiod binary knapsack problem (MPBKP) is given by a horizon length \( T \), a non-decreasing vector of knapsack sizes \( (c_1, \ldots, c_T) \) where \( c_t \) denotes the cumulative size for periods \( 1, \ldots, t \), and a list of \( n \) items. Each item is a triple \((r, q, d)\) where \( r \) denotes the reward or value of the item, \( q \) its size, and \( d \) denotes its time index (or, deadline). The goal is to choose, for each deadline \( t \), which items to include to maximize the total reward, subject to the constraints that for all \( t = 1, \ldots, T \), the total size of selected items with deadlines at most \( t \) does not exceed the cumulative capacity of the knapsack up to time \( t \).

We also consider the multiperiod binary knapsack problem with soft capacity constraints (MPBKP-S) where the capacity constraints are allowed to be violated by paying a penalty that is linear in the violation. The goal of MPBKP-S is to maximize the total profit, which is the total reward of the selected items less the total penalty. Finally, we consider the multiperiod binary knapsack problem with soft stochastic capacity constraints (MPBKP-SS), where the non-decreasing vector of knapsack sizes \( (c_1, \ldots, c_T) \) follow some arbitrary joint distribution but we are given access to the profit as an oracle, and we must choose a subset of items to maximize the total expected profit, which is the total reward less the total expected penalty.

For MPBKP, we exhibit a fully polynomial-time approximation scheme that achieves \((1 + \epsilon)\) approximation with runtime \(\tilde{O}\left(\min\left\{ n + \frac{T^3}{\epsilon^2}, n + \frac{T^2}{\epsilon}, \frac{nT}{\epsilon}, \frac{n^2}{\epsilon^3}\right\}\right)\); for MPBKP-S, the \((1 + \epsilon)\) approximation can be achieved in \(O\left(\frac{n \log n}{\epsilon} \cdot \min\left\{ \frac{T}{\epsilon}, n \right\}\right)\). To the best of our knowledge, our algorithms are the first FPTAS for any multiperiod version of the Knapsack problem since its study began in 1980s. For MPBKP-SS, we prove that a natural greedy algorithm is a 2-approximation when items have the same size. Our algorithms also provide insights on how other multiperiod versions of the knapsack problem may be approximated.
1 Introduction

Knapsack problems are a classical category of combinatorial optimization problems, and have been studied for more than a century (Mathews, 1896). They have found wide applications in various fields (Kellerer et al., 2004), such as selection of investments and portfolios, selection of assets, finding the least wasteful way to cut raw materials, etc. One of the most commonly studied problem is the so-called 0-1 knapsack problem, where a set of $n$ items are given, each with a reward and a size, and the goal is to select a subset of these items to maximize the total reward, subject to the constraint that the total size may not exceed some knapsack capacity. It is well-known that the 0-1 knapsack problem is NP-complete. However, the problem was shown to possess fully polynomial-time approximation schemes (FPTASs), i.e., there are algorithms that achieve $(1 + \epsilon)$ factor of the optimal value for any $\epsilon \in (0, 1)$, and take polynomial time in $n$ and $1/\epsilon$.

The first published FPTAS for the 0-1 knapsack problem was due to Ibarra and Kim (1975) where they achieve a time complexity $\tilde{O}(n + (1/\epsilon^4))$ by dividing the items into a class of “large” items and a class of “small” items. The problem is first solved for large items only, using the dynamic program approach, with rewards rounded down using some discretization quantum (chosen in advance), and the small items are added later. Lawler (1979) proposed a more nuanced discretization method to improve the polylogarithmic factors. Since then, improvements have been made on the dynamic program for large items (Kellerer and Pferschy, 2004; Rhee, 2015). Most recently, the FPTAS has been improved to $\tilde{O}(n + (1/\epsilon)^{9/4})$ in Jin (2019).

In this paper, we study three extensions of the 0-1 knapsack problem. First, we consider a multiperiod version of the 0-1 knapsack problem, which we call the multiperiod binary knapsack problem (MPBKP). There is a horizon length $T$ and a vector of knapsack sizes $(c_1, \ldots, c_T)$, where $c_t$ is the cumulative size for periods $1, \ldots, t$ and is non-decreasing in $t$. We are also given a list of $n$ items, each associated with a triple $(r, q, d)$ where $r$ denotes the reward or value of the item, $q$ its size, and $d$ denotes its time index (or, deadline). The goal is to choose a reward maximizing set of items to include such that for any $t = 1, \ldots, T$, the total size of selected items with deadlines at most $t$ does not exceed the cumulative capacity of the knapsack up to time $t$. The application that motivates this problem is a seller who produces $(c_t - c_{t-1})$ units of a good in time period $t$, and can store unsold goods for selling later. The seller is offered a set of bids, where each bid includes a price ($r$), a quantity demanded ($q$), and a time at which this quantity is needed. The problem of deciding the revenue maximizing subset of bids to accept is exactly MPBKP.

The second extension we consider is the multiperiod binary knapsack problem with soft capacity constraints (MPBKP-S) where at each period the capacity constraint is allowed to be violated by paying a penalty that is linear in the violation. The goal of MPBKP-S is then to maximize the total profit, which is the total reward of the selected items less the total penalty. In this case, the seller can procure goods from outside at a certain rate if his supply is not enough to fulfill the bids he accepts, and wants to maximize his profit.

The third extension we consider is the multiperiod binary knapsack problem with soft stochastic capacity constraints (MPBKP-SS) where the non-decreasing vector of knapsack sizes $(c_1, \ldots, c_T)$ follows some arbitrary joint distribution given as the set of sample paths of the possible realizations and their probabilities. We select the items before realizations of any of these random incremental capacities to maximize the total expected profit, which is the total reward of selected items less the total expected penalty. In this case, the production of the seller at each time is random, but he has to select a subset of bids before realizing his supply. Again, the seller can procure capacity from outside at a certain rate if his realized supply is not enough to fulfill the bids he accepts, and wants to maximize his expected profit.

We note that MPBKP is also related to a number of other multiperiod versions of the knapsack problem in
literature. The multiperiod knapsack problem (MPKP) proposed by Faaland (1981) has the same structure as MPBKP, except that in Faaland (1981), each item can be repeated multiple times, i.e., the decision variables for each item is not binary, but any nonnegative integer (in the single-period case, this is called the unbounded knapsack problem (Andonov et al., 2000)). To the best of our knowledge, there has been no further studies on MPKP since Faaland (1981). In the multiple knapsack problem (MKP), there are \( m \) knapsacks, each with a different capacity, and items can be inserted to any knapsacks (subject to its capacity constraints). It has been shown in Chekuri and Khanna (2005) that MKP does not admit an FPTAS, but an efficient polynomial time approximation scheme (EPTAS) has been found in Jansen (2012), with runtime depending polynomially on \( n \) but exponentially on \( 1/\epsilon \). The incremental knapsack problem (IKP) is another multiperiod version of the knapsack problem (Hartline and Sharp, 2006), where the knapsack capacity increases over time, and each selected item generates a reward on every period after its insertion, but this reward is discounted over time. Unlike MPBKP, items do not have deadlines and can be selected anytime throughout the \( T \) periods. A PTAS for the IKP when the discount factor is 1 (time invariant, referred to as IIKP) and \( T = O(\sqrt{\log n}) \) has been found in Bienstock et al. (2013), and it has been shown that IIKP is strongly NP-hard. Later, Faenza and Malinovic (2018) proposed the first PTAS for IIKP regardless of \( T \), and Della Croce et al. (2019) proposed an PTAS for IKP when \( T \) is a constant. Most recent developments of IKP include Aouad and Segev (2020); Faenza et al. (2020). Other similar problems and/or further extensions include the multiple-choice multiperiod knapsack problem (Lin and Chen, 2010; Lin and Wu, 2004; Randeniya, 1994), the multiperiod multi-dimensional knapsack problem (Lau and Lim, 2004), the multiperiod precedence-constrained knapsack problem (Moreno et al., 2010; Samavati et al., 2017), to name a few.

Our main contributions of this paper are two-fold. First, from the perspective of model formulation, we propose the MPBKP and its generalized versions MPBKP-S and MPBKP-SS. Despite the fact that there are a number of multiperiod/multiple versions of knapsack problems, including those mentioned above (many of which are strongly NP-hard), the MPBKP and MPBKP-S we proposed here are the first to admit an FPTAS among any multiperiod versions of the classical knapsack problem since their initiation back in 1980s. With these results, it is thus interesting to see where the boundary lies between these multiperiod problems that admit an FPTAS and those problems that do not admit an FPTAS. Second, the algorithms we propose for both MPBKP and MPBKP-S are generalized from the ideas of solving 0-1 knapsack problems, but with nontrivial modifications as we will address in the following sections. For MPBKP-SS, we propose a greedy algorithm that achieves 2-approximation for the special case when all items have the same size.

The rest of this paper is organized as follows. In Section 2 we formally write the three problems in mathematical programming form. The FPTAS for MPBKP is proposed in Section 3 and the FPTAS for MPBKP-S is proposed in Section 4. Alternative algorithms for both problems are also provided in Appendix. A greedy algorithm for a special case of MPBKP-SS is proposed in Section 5. All proofs are left to Appendix but we provide proof ideas in the main body.

2 Problem Formulation and Main Results

In this section, we formally introduce the Multiperiod Binary Knapsack Problem (MPBKP), as well as the generalized versions: the Multiperiod Binary Knapsack Problem with Soft capacity constraints (MPBKP-S), and Multiperiod Binary Knapsack Problem with Soft Stochastic Capacity constraints (MPBKP-SS).
2.1 Multiperiod binary Knapsack problem (MPBKP)

An instance of MPBKP is given by a set of $n$ items, each associated with a triple $(r_i, q_i, d_i)$, and a sequence of knapsack capacities $\{c_1, \ldots, c_T\}$. For each item $i$, we get reward $r_i$ if and only if $i$ is included in the knapsack by time $d_i$. We assume that $r_i \in \mathbb{N}$, $q_i \in \mathbb{N}$ and $d_i \in [T] := \{1, \ldots, T\}$. The knapsack capacity at time $t$ is $c_t$, and by convention $c_0 = 0$. The MPBKP can be written in the integer program (IP) form:

$$\max_x z = \sum_{i=1}^n r_i x_i \quad \text{(1a)}$$

subject to:

$$\sum_{j : d_j \leq t} q_j x_j \leq c_t, \quad \forall t = 1, \ldots, T \quad \text{(1b)}$$

$$x_i \in \{0, 1\}, \quad \forall i = 1, \ldots, n \quad \text{(1c)}$$

where $x_i$’s are binary decision variables, i.e., $x_i$ is 1 if item $i$ is included in the knapsack and is 0 otherwise. In (1), we aim to pick a subset of items to maximize the objective function, which is the total reward of picked items, subject to the constraints that by each time $t$, the total size of picked items with deadlines up to $t$ does not exceed the knapsack capacity at time $t$, which is $c_t$. For each $t \in [T]$, let $I(t) := \{i \in [n] | d_i = t\}$ denote the set of items with deadline $t$. Note that without loss of generality, we may assume that $I(t) \neq \emptyset$, $\forall t$ and $c_t > 0$. We further note that the decision variables $x_i$’s in (1) are binary, but if we relax this to any nonnegative integers, the problem becomes the so-called multiperiod knapsack problem (MPKP) as in Faaland (1981). Our first main result is the following theorem on MPBKP.

**Theorem 1.** An FPTAS exists for MPBKP. Specifically, there exists a deterministic algorithm that achieves $(1+\epsilon)$-approximation in $\tilde{O}\left(\min\left\{n + \frac{T^{1.25}}{\epsilon^2}, n + \frac{T^2}{\epsilon^3}, n^3, \frac{n^2}{\epsilon}\right\}\right)$.

As we will see shortly, MPBKP can be viewed as a special case of MPBKP-S. In Section 3, we will provide an approximation algorithm for MPBKP with runtime $\tilde{O}\left(n + \frac{T^{3.25}}{\epsilon^2}\right)$. An alternative algorithm with runtime $\tilde{O}\left(n + \frac{T^3}{\epsilon}\right)$ is provided in Appendix B. In Section 4, we will provide an approximation algorithm for MPBKP-S with runtime $\tilde{O}\left(\frac{nT}{\epsilon}\right)$, which is also applicable to MPBKP.

2.2 Multiperiod binary Knapsack problem with soft capacity constraints (MPBKP-S)

In MPBKP-S, the capacity constraints in (1) no longer exist, i.e., the total size of selected items at each time step is allowed to be greater than the total capacity up to that time, however, there is a penalty rate $B_t \in \mathbb{N}$ for each unit of overflow at period $t$. We assume that $B_t > \max_{i \in [n]} \frac{r_i}{q_i}$ to avoid trivial cases (any item with $\frac{r_i}{q_i} \geq B_t$ and $d_i \leq t$ will always be added to generate more profit). In the IP form, MPBKP-S can be written as

$$\max_{x,y} \sum_{i \in [n]} r_i x_i - \sum_{t=1}^T B_t y_t \quad \text{(2a)}$$

subject to:

$$\sum_{i \in I(1) \cup \ldots \cup I(t)} q_i x_i - \sum_{s=1}^t y_s \leq c_t, \quad \forall t : 1 \leq t \leq T \quad \text{(2b)}$$

$$x_i \in \{0, 1\}, \quad y_t \geq 0, \quad \text{(2c)}$$
where the decision variables $y_t, t = 1, \ldots, T$ represent the units of overflow at time $t$, and $c_t - c_{t-1}$ is the incremental capacity at time $t$. The objective is to choose a subset of the $n$ items to maximize the total profit, which is the sum of the rewards of the selected items minus the sum of penalty paid at each period, and the constraints enforce that the total size of accepted items by the end of each period must not exceed the sum of the cumulative capacity and the units of overflow. Our second main result is the following theorem on MPBKP-S.

**Theorem 2.** An FPTAS exists for MPBKP-S. Specifically, there exists an algorithm which achieves $(1 + \epsilon)$-approximation in $O \left( \frac{n \log n}{\epsilon} \cdot \min \{ T, n \} \right)$.

In section 4 we will present an approximation algorithm for solving MPBKP-S with time complexity $O \left( nT \log n \epsilon^2 \right)$.

An alternative FPTAS with runtime $O \left( \frac{n^2}{\epsilon^2} \right)$ is provided in Appendix C. For the ease of presentation, our algorithms and analysis are presented for the case $B_t = B$, but they can be generalized to the heterogeneous $\{B_1, \ldots, B_T\}$ in a straightforward manner. It is worth noting that the algorithm for MPBKP that we introduce in section 3 does not extend to MPBKP-S, and we will make this clear in the beginning of section 4.

### 2.3 Multiperiod Binary Knapsack Problem with Soft Stochastic Capacity Constraints (MPBKP-SS)

The MPBKP-SS formulation is similar to (2), except that the vector of knapsack sizes $(c_1, \ldots, c_T)$ follows some arbitrary joint distribution given to the algorithm as the set of possible sample path (realization) of knapsack sizes and the probability of each sample path. We use $\omega$ to index sample paths which we denote by $\{c_t(\omega)\}$, $p(\omega)$ as the probability of sample path $\omega$, and $\Omega$ as the set of possible sample paths. The goal is to pick a subset of items before the realization of $\omega$ so as to maximize the expected total profit, which is the sum of the rewards of the selected items deducted by the total (expected) penalty. For a sample $\omega \in \Omega$ let $y_t(\omega)$ be the overflow at time $t$. Then, we can write the problem in IP form as:

$$\max_{x,y} \sum_{i \in [n]} r_i x_i - \mathbb{E}_\omega \left[ B_t \cdot \sum_{t=1}^{T} y_t(\omega) \right]$$

s.t. $\sum_{i \in \mathcal{I}(1) \cup \cdots \cup \mathcal{I}(t)} q_i x_i - \sum_{s=1}^{t} y_s(\omega) \leq c_t(\omega), \quad \forall \omega \in \Omega, 1 \leq t \leq T$

$x_i \in \{0, 1\}, \quad y_t \geq 0$

Our third main result is the following theorem on MPBKP-SS, which asserts a greedy algorithm for the special case when all items are of the same size. Details will be provided in Section 5.

**Theorem 3.** If $q_i = q$ for all $i \in [n]$, then there exists a greedy algorithm that achieves 2-approximation for MPBKP-SS in $O \left( n^2 T |\Omega| \right)$.

We further note that both MPBKP-S and MPBKP-SS are special cases of non-monotone submodular maximization which is not non-negative, for which not many general approximations are known. In that sense, studying these problems would be an interesting direction to develop techniques for it.
3 FPTAS for MPBKP

In this section, we provide an FPTAS for the MPBKP with time complexity $\tilde{O}\left(n + \frac{T^{3.25}}{\epsilon^{2.25}}\right)$. We will apply the “functional approach” as used in Chan (2018). The main idea is to use the results on function approximations (Chan, 2018; Jin, 2019) as building blocks – for each period we approximate one function that gives, for every choice of available capacity, the maximum reward obtainable by selecting items in that period. We then combine “truncated” version of these functions using (max, +)-convolution. This idea, despite its simplicity, allows us to obtain an FPTAS for MPBKP. Such a result should not be taken as granted – as we will see in the next section, this method does not apply for MPBKP-S, even though it is just a slight generalization of MPBKP.

We begin with some preliminary definitions and notations. For a given set of item rewards and sizes, $\mathcal{I} = \{(r_1, q_1), \ldots, (r_n, q_n)\}$, define the function

$$f_{\mathcal{I}}(c) := \max_{x_1, \ldots, x_n} \left\{ \sum_{i \in \mathcal{I}} r_i x_i : \sum_{i \in \mathcal{I}} q_i x_i \leq c, x_1, \ldots, x_n \in \{0, 1\} \right\}$$

(4)

for all $c \geq 0$, and $f_{\mathcal{I}}(c) := -\infty$ for $c < 0$. The function $f_{\mathcal{I}}$ is a nondecreasing step function, and the number of steps is called the complexity of that function. Further, for any $\mathcal{I} = \mathcal{I}_1 \cup \mathcal{I}_2$, i.e., $\mathcal{I}$ being a disjoint union of $\mathcal{I}_1$ and $\mathcal{I}_2$, we have that $f_{\mathcal{I}} = f_{\mathcal{I}_1} \oplus f_{\mathcal{I}_2}$, where $\oplus$ denotes the (max, +)-convolution: $(f \oplus g)(c) = \max_{c' \in \mathbb{R}}(f(c') + g(c - c'))$.

We define the truncated function $f_{\mathcal{I}}^{c'}$ as follows:

$$f_{\mathcal{I}}^{c'}(c) = \begin{cases} f_{\mathcal{I}}(c) & c \leq c', \\ -\infty & c > c'. \end{cases}$$

(5)

Recall that we denote the set of items with deadline $t$ by $\mathcal{I}(t)$. We next define the function $f_t$ as follows:

$$f_t := \begin{cases} f_{\mathcal{I}(1)}^{c_1} & t = 1, \\ (f_{t-1} \oplus f_{\mathcal{I}(t)})^{c_t} & t \geq 2. \end{cases}$$

(6)

In words, each function value of $f_t(c)$ corresponds to a feasible, in fact an optimal, solution $x$ for items with deadline at most $t$ as the next proposition shows.

Proposition 1. Let $x^*$ be the optimal solution for MPBKP (1). We have that the optimal value of (1), $\sum_{i \in [n]} r_i x_i^*$, satisfies $\sum_{i \in [n]} r_i x_i^* = f_T(c_T)$.

Proposition 1 implies that, to obtain an approximately optimal solution for MPBKP (1), it is sufficient to have a good approximation for the function

$$f_T = \left( \cdots \left( \left( f_{\mathcal{I}(1)}^{c_1} \oplus f_{\mathcal{I}(2)}^{c_2} \right) \oplus f_{\mathcal{I}(3)}^{c_3} \right) \cdots \oplus f_{\mathcal{I}(T)}^{c_T} \right)^{c_T}.$$  

(7)

We say that a function $\tilde{f}$ approximates the nonnegative function $f$ with factor $1 + \epsilon$ if $\tilde{f}(c) \leq f(c) \leq (1 + \epsilon)\tilde{f}(c)$ for all $c \in \mathbb{R}$. It should be clear that if $\tilde{f}$ approximates $f$ with factor $1 + \epsilon$ and $\tilde{g}$ approximates $g$ with factor $1 + \epsilon$, then $\tilde{f} \oplus \tilde{g}$ approximates $f \oplus g$ with factor $1 + \epsilon$. We then introduce the following result from Jin (2019) for 0-1 Knapsack problem.
Lemma 1 (Jin (2019)). Given a set $I = \{(r_1, q_1), \ldots, (r_n, q_n)\}$, we can obtain $\tilde{f}_t$ that approximates $f_t$ (defined in (4)) with factor $1 + \epsilon$ and complexity $\tilde{O} \left( \frac{1}{\epsilon^2} \right)$ in $\tilde{O} \left( n + (1/\epsilon)^{2.25} \right)$. 

With the above lemma, we present Algorithm 1 for MPBKP.

**Algorithm 1** FPTAS for MPBKP

| Input: $\epsilon, [n], c_1, \ldots, c_T$ | Output: $\tilde{f}_t$ | $\triangleright$ Set of items to be packed, cumulative capacities $\triangleright$ Approximation of function $f_t$ |
|------------------------------------------|-----------------|-----------------|
| 1: Discard all items with $r_i \leq \frac{1}{n} \max_j r_j$ and relabel the items | $r_0 \leftarrow \min_i r_i$ | $\triangleright$ Lower bound of solution value |
| 2: $m \leftarrow \lceil \log_{1+\epsilon} \frac{1}{\epsilon^2} \rceil$ | $\triangleright$ number of distinct rewards to be considered, each in the form $r_i \cdot (1 + \epsilon)^k$ |
| 4: Obtain $\tilde{f}_{I(t)}$ that approximates $f_{I(t)}$ with factor $(1 + \epsilon)$ using Lemma 1 | $\tilde{f}_1 := \tilde{f}_{I(t)}$ | $\triangleright \tilde{f}_1$ has complexity at most $m = \tilde{O} \left( \frac{1}{\epsilon^2} \right)$ |
| 5: for $t = 2, \ldots, T$ do | $l \leftarrow \text{complexity of } \tilde{f}_{I(t)}$ | $\triangleright l = \tilde{O} \left( \frac{1}{\epsilon^2} \right)$ |
| 6: Obtain $\tilde{f}_{I(t)}$ that approximates $f_{I(t)}$ with factor $(1 + \epsilon)$ using Lemma 1 | $\tilde{f}_t \leftarrow \left( \tilde{f}_{I(t)} \right)^{m} \cdot (1 + \epsilon)^{-t}$, taking $m \cdot l$ time | $\triangleright \tilde{f}_t$ has complexity $\tilde{O} \left( \frac{1}{\epsilon^2} \right)$ |
| 7: Compute (all breakpoints and their values of) $\tilde{f}_t := \left( \tilde{f}_{I(t)} \right)^{m} \cdot (1 + \epsilon)^{-t}$, taking $m \cdot l$ time | $\tilde{f}_t \leftarrow \min_{j} r_j$ and approximate $f_t$ for all $t$ in period $l$ | $\triangleright \tilde{f}_t$ has complexity at most $m = \tilde{O} \left( \frac{1}{\epsilon^2} \right)$ |

We now describe the intuition behind Algorithm 1. We first discard all items with reward $r_i \leq \frac{1}{n} \max_j r_j$. The maximum we could lose is $n \cdot \frac{1}{n} \max_j r_j = \epsilon \max_j r_j$, which is at most $\epsilon$ fraction of the optimal value. We next obtain all $\tilde{f}_{I(t)}$, for all $t = 1, \ldots, T$, that approximate $f_{I(t)}$ (as defined in (4)) within a $(1 + \epsilon)$ factor. These functions $\tilde{f}_{I(t)}$ have complexity $\tilde{O} \left( \frac{1}{\epsilon} \right)$, which is a nonnegative integer. Note that $r_0$ is a lower bound of any solution value. After discarding small-reward items, we have that $\frac{\max_j r_j}{r_0} \leq \frac{n}{\epsilon}$, which implies that $n \max_j r_j = \frac{n^2}{\epsilon} r_0$ is an upper bound for the optimal solution value. Therefore, after rounding down the function values of $\tilde{f}_2$ and obtaining $\tilde{f}_2$, there are at most $\log_{1+\epsilon} \frac{n^2}{\epsilon} \approx \frac{1}{\epsilon} \log \frac{n^2}{\epsilon}$ different values on $\tilde{f}_2$. Now we have brought down the complexity of $\tilde{f}_2$ again to $\tilde{O} \left( \frac{1}{\epsilon} \right)$, at an additional $(1 + \epsilon)$ factor loss in the approximation error. We then move to period 3 and continue this pattern of $(\max, +)$-convolution, truncation, and rounding down. In the end, when we reach period $T$, $\tilde{f}_T$ will only contain feasible solutions to (1), and approximate $f_T$ with total approximation factor of $(1 + \epsilon)^T \approx (1 + T \epsilon)$. Formally, we have the following lemma which shows the approximation factor of $\tilde{f}_t$ for $f_t$.

**Lemma 2.** Let $\tilde{f}_t$ be the functions obtained from Algorithm 1, and let $f_t$ be defined as in (6). Then, $\tilde{f}_t$ approximates $f_t$ with factor $(1 + \epsilon)^t$, i.e., $\tilde{f}_t(c) \leq f_t(c) \leq (1 + \epsilon)^t \tilde{f}_t(c)$ for all $0 \leq c \leq c_t$. 

Lemma 2 and Proposition 1 together imply that $\tilde{f}_T(c_T)$, obtained from Algorithm 1, approximates the optimal value of MPBKP (1) by a factor of $(1 + \epsilon)^T \approx (1 + T \epsilon)$. In Algorithm 1, obtaining $\tilde{f}_{I(t)}$ for all $t = 1, \ldots, T$ takes time $\tilde{O} \left( n + T/\epsilon^{2.25} \right)$, computing the $(\max, +)$-convolution on $\tilde{f}_{I(t)}$ for all $t$ take time $T \cdot m \cdot l = \tilde{O} \left( T/\epsilon^2 \right)$. Therefore, Algorithm 1 has runtime $\tilde{O} \left( n + T/\epsilon^{2.25} \right)$. As a result, we have the following proposition.
Proposition 2. Taking \( \epsilon' = 2T \epsilon \), Algorithm 1 achieves \((1 + \epsilon')\)-approximation for MPBKP in \( \tilde{O}(n + \frac{T^{3.25}}{\epsilon^{2.75}}) \).

4 FPTAS for MPBKP-S

In this section, we provide an FPTAS for the MPBKP-S with time complexity \( \mathcal{O}\left(\frac{n^{2} \log n}{\epsilon^2}\right) \). An alternative FPTAS with time complexity \( \mathcal{O}\left(\frac{n \log n}{\epsilon^2}\right) \) is provided in Appendix C. Combining the two, we show that our algorithms achieve \((1 + \epsilon)\) approximation ratio in time \( \mathcal{O}\left(\frac{n \log n \cdot \min\{\frac{T}{\epsilon}, n\}}{\epsilon^2}\right) \), which proves Theorem 2. We should note that the algorithm in the previous section does not apply here: we could similarly define a function which gives the maximum profit (=reward–penalty) under a given capacity constraint, but the main obstacle is on the \((\max, +)-\)convolution because profit does not “add up”. In other words, the total profit we earn by selecting items in the set \( S_1 \cup S_2 \) is not the sum of the profits we earned by selecting \( S_1 \) and \( S_2 \) separately. For this reason, we can no longer rely on the techniques used in function approximation and \((\max, +)-\)convolution as in Chan (2018); Jin (2019). Instead, our main idea is motivated by the techniques that originated from earlier papers (Ibarra and Kim, 1975; Lawler, 1979), but adapting their technique to MPBKP-S requires significant modifications as we show in this section. We restrict our presentation to the case \( B_t = B \) for readability, but our algorithms and analysis generalize in a straightforward manner when the penalties for buying capacity are heterogeneous \( \{B_1, \ldots, B_T\} \) (by replacing \( B \) with \( \min_{r \leq t} B_r \) in the calculations of profit/penalty at period \( t \) on line 7 of Algorithm 2).

Preliminaries: We first introduce some notation. From now on, let \( \mathcal{R}(S) := \sum_{i \in S} T_i \). The optimal solution set to (2) is denoted by \( S^* \). The total profit earned can be expressed as a function of the solution set \( S \):

\[
\mathcal{P}(S) = \mathcal{R}(S) - B \cdot \sum_{t=1}^{T} \left[ \sum_{j \in S \cap \mathcal{I}(t)} q_j - \max \left\{ c_t - \sum_{j \in S, d_j \leq t} q_j, c_t - c_{t-1} \right\} \right]^{+}, \tag{8}
\]

Let \( p_i \) be the profit of item \( i \), which is defined as the profit earned if we select only \( i \), i.e., \( p_i = r_i - B \cdot (q_i - c_{d_i})^+ \). Without loss of generality, we assume that each item \( i \) is by itself profitable, i.e., \( p_i \geq 0 \), so one profitable solution would be \( \{i\} \). Let \( P := \max_i p_i \) and \( \mathcal{P} := \sum_{i \in [n]} p_i \). The following bounds on \( \mathcal{P}(S^*) \) follow:

\[
P \leq \mathcal{P}(S^*) \leq \mathcal{P} \leq nP. \tag{9}
\]

Partition of items: We partition the set of items \([n]\) into two sets: a set of “large” items \( \mathcal{I}_L \) and a set of “small” items \( \mathcal{I}_S \) such that we can bound the number of large items in any optimal solution. The main idea is to use dynamic programming to pick the large items in the solution, and a greedy heuristic for ‘padding’ this partial solution with small items. The criterion for small and large items is based on balancing the permissible error \( \epsilon \mathcal{P}(S^*) \) equally in filling large items and filling small items. Instead of first packing all large items and then all small items, we consider items in the order of their deadlines, and for each deadline \( t \), the large items are selected first and then the small items are selected greedily in order of their reward densities. As a result, the approximation error due to large items overall will be \( \frac{1}{2} \epsilon \mathcal{P}(S^*) \) and the error due to the small items with each deadline will be \( \frac{1}{2T} \epsilon \mathcal{P}(S^*) \). This gives a total approximation error of \( \frac{1}{2} \epsilon \mathcal{P}(S^*) + T \cdot \frac{1}{2T} \epsilon \mathcal{P}(S^*) = \epsilon \mathcal{P}(S^*) \).

Suppose that we can find some \( P_0 \) that satisfies (10).

\[
P_0 \leq \mathcal{P}(S^*) \leq 2P_0. \tag{10}
\]
Then, the set of items is partitioned as follows.

\[ I_L := \left\{ i \in [n] \mid p_i \geq \frac{1}{2T} \epsilon P_0 \right\}; \quad I_S := \left\{ i \in [n] \mid p_i < \frac{1}{2T} \epsilon P_0 \right\}. \] (11)

This partition is computed in \( O(n) \) time and is not the dominant term in time complexity. Let \( n_L = |I_L| \) and \( n_S = |I_S| \), so that \( n_L + n_S = n \). Further, let

\[ I_L(t) := \{ i \in S_L \mid d_i = t \}, \quad \text{and} \quad I_S(t) := \{ i \in S_S \mid d_i = t \} \]
denote the set of large and small items, respectively, with deadline \( t \). We will assume that the items in \( I_L \) are indexed in non-decreasing order of their deadlines, i.e., \( \forall i, j \in I_L \) such that \( j \geq i \), we have that \( d_i \leq d_j \). Denote by \( I_L(t) \) as the index of the last item with deadline \( t \), i.e., \( I_L(t) := \max_{i \in S_L \cap I_L(t)} i \). For each time \( t \), we will also sort the small items in \( I_S(t) \) according to their reward densities, i.e., \( \forall i < j \) and \( i, j \in I_S(t) \), \( \frac{c_i}{q_i} \geq \frac{c_j}{q_j} \). This sorting only takes place once for each guess \( P_0 \), and does not affect our overall time complexity result.

### Algorithm 2 DP on large items for MPBKP-S

**Input:**
- \( \bar{I}_L, \Delta c \) \quad \triangleright \text{Set of (large) items to be packed, additional capacity available for packing}
- \( \bar{A}(p) \) for all \( p = \{0, 1, \ldots, \left\lfloor \frac{16T}{c} \right\rfloor \} \cdot \kappa \)

**Output:**
- \( \bar{A}(I_L, p) \) for all \( p = \{0, 1, \ldots, \left\lfloor \frac{16T}{c} \right\rfloor \} \cdot \kappa \)

1: Initialize \( \forall p : \bar{A}(0, p) := A(p) + \Delta c \)
2: for \( i = 1, \ldots, I_L \) do
3: for \( p = \{0, 1, \ldots, \left\lfloor \frac{16T}{c} \right\rfloor \} \cdot \kappa \) do
4: \( \bar{A}(i, p) := \bar{A}(i - 1, p) \) \quad \triangleright \text{If reject item } i
5: end for
6: for \( p = \{0, 1, \ldots, \left\lfloor \frac{16T}{c} \right\rfloor \} \cdot \kappa \) do
7: \( p = \bar{p} + \bar{r}_i - \left[ B \left( q_i - \max \left\{ 0, \bar{A}(i - 1, \bar{p}) \right\} \right) + \right]_\kappa \)
8: \( \bar{A}(i, p) = \max \left\{ \bar{A}(i, p), \bar{A}(i - 1, \bar{p}) - q_i \right\} \) \quad \triangleright \text{Accept } i
9: end for
10: for \( p = \left\{ \left\lfloor \frac{16T}{c} \right\rfloor, \left\lfloor \frac{16T}{c} \right\rfloor + 1, \ldots, 1 \right\} \cdot \kappa \) do
11: if \( \bar{A}(i, p - \kappa) < \bar{A}(i, p) \) then
12: \( \bar{A}(i, p - \kappa) = \bar{A}(i, p) \)
13: end if
14: end for
15: end for

**Algorithm overview:** Our FPTAS algorithm is given in Algorithm 5 which uses a doubling trick to guess the value of \( P_0 \) satisfying (10), and for each guess uses Algorithm 4 as a subroutine. Algorithm 4 is the main algorithm for MPBKP-S, which first selects the items with deadline 1, then the items with deadline 2, and so on. For each deadline \( t \), we maintain two sets of partial solutions: the first, \( \bar{A}_t(p) \), corresponds to an approximately optimal (in terms of leftover capacity carried forward to time \( t + 1 \)) subset of large and small items with deadline at most \( t \) and some rounded profit \( p \); and the second \( \tilde{A}_t(p) \) corresponds to the optimal appending of large items with deadline \( t \) to the approximately optimal set of solutions corresponding to \( \tilde{A}_{t-1} \).

Given \( \tilde{A}_{t-1} \), we first select large items from \( I_L(t) \) using dynamic programming to obtain \( \tilde{A}_t \), which is done in Algorithm 2. In other words, given the partial solutions \( \tilde{A}_{t-1}(\bar{p}) \) for all \( \bar{p} \in \{0, 1, \ldots, \left\lfloor \frac{16T}{c} \right\rfloor \} \cdot \kappa \), \( \tilde{A}_t(p) \) is the maximum capacity left when earning rounded profit (precise definition given in (14)) \( p \) by adding items in
The small items in $\tilde{I}_S(t)$ are sorted according to their reward densities, and are added to the solution of $\tilde{A}_t(\bar{p})$ one by one. After each addition of a small item, if the new total rounded reward is $p$, we compute the leftover capacity with current $\tilde{A}_t(p)$, and update $\tilde{A}_t(p)$ with the new solution if it has more leftover capacity. We continue this add-and-compare (and possibly update) until we reach the situation where adding the next small item overflows the available capacity.

Intuitively, for any amount of capacity available to be filled by small items, and a minimum increase in profit, the optimal solution either packs a single item from $I_S(t) \setminus \tilde{I}_S(t)$ in which case the loss by ignoring items in this set is bounded by the maximum reward of any small item, or the optimal solution only contains items from $\tilde{I}_S(t)$ in which case the space used by this optimal set of items is lower bounded by the a fractional packing of the highest density items in $I_S(t)$. During Algorithm 3, one of the solutions we would consider would be the integral items of this fractional solution, and lose at most $\frac{1}{2\epsilon} P_0 t$ in profit, and obtain a solution with still smaller space used (more leftover capacity) than the fractional solution. Accumulation of these errors for $t$ periods then will give us the invariant: the partial solution $\tilde{A}_t(p)$ obtained as above has more leftover capacity than any solution obtained by selecting items from $\cup_{t'=1}^t I_L(t')$ with rounded rewards and rounded penalties, and items from $\cup_{t'=1}^t I_S(t')$ with original (unrounded) rewards such that the rounded total profit is at least $p + \frac{1}{2\epsilon} P_0 t + \kappa t$. 

---

**Algorithm 3** Greedy on small items for MPBKP-S

```plaintext
Input: $I_S, \bar{A}(p)$ for all $p = \{0, 1, \ldots, \left\lceil \frac{\epsilon P_0}{cL} \right\rceil \} \cdot \kappa$.  
Output: $\tilde{A}(p)$ for all $p = \{0, 1, \ldots, \left\lceil \frac{\epsilon P_0}{cL} \right\rceil \} \cdot \kappa$  

1: Initialize $\forall p: \bar{A}(p) = A(p)$  
2: for $p = \{0, 1, \ldots, \left\lceil \frac{\epsilon P_0}{cL} \right\rceil \} \cdot \kappa$ do
   
   // Filter out small items with size larger than $A(p)$
3:   $\tilde{I}_S \leftarrow \emptyset$
4:   for $i \in I_S$ do
5:     if $A(p) \geq q_i$ then
6:       $\tilde{I}_S \leftarrow \tilde{I}_S \cup \{i\}$
7:   end if
8: end for
9: $R_{o'} = 0, q_{o'} = 0$, and relabel the items in $\tilde{I}_S$ as $\{1', \ldots, |\tilde{I}_S|\}'$ (in decreasing order of reward density)
10: for $i' = 1', \ldots, |\tilde{I}_S|'$ do
11:   $R_{o'} = R_{(i-1)'} + r_{i'}$
12:   $q_{o'} = q_{(i-1)'} + q_{i'}$
13: end for
14: // Add small items using Greedy algorithm
15: for $i' = 1', \ldots, |\tilde{I}_S|'$ do
16:   if $\tilde{q}_{i'} \leq \bar{A}(\tilde{p})$ then
17:     $p = \left\lfloor \tilde{p} + R_{o'} \right\rfloor$
18:     $\tilde{A}(p) = \max \left\{ \tilde{A}(p), \bar{A}(\tilde{p}) - \tilde{q}_{i'} \right\}$
19:   end if
20: end for
21: end for

$\tilde{I}_L(t)$. We then use a greedy heuristic to pick small items from $I_S(t)$ to obtain $\tilde{A}_t$, which is done in Algorithm 3. Specifically, our goal in Algorithm 3 is to obtain the partial solutions $\tilde{A}_t(\cdot)$ given the partial solutions $\bar{A}_t(\cdot)$ by packing the small items $I_S(t)$. We initialize $\bar{A}_t(\tilde{p})$ with $\bar{A}_t(p)$, and for each $\tilde{p}$ we try to augment the solution corresponding to $\bar{A}_t(p)$ using a subset $\tilde{I}_S(t) \subseteq I_S(t)$ defined as

$\tilde{I}_S(t) := \{ i \in I_S(t) \mid q_i \leq A_t(\tilde{p}) \}$. 
```
Algorithm 4 DP on large items and Greedy on small items for MPBKP-S

1: Define $\kappa = \frac{c_\delta P_0}{2}$
2: Define $\tilde{r}_1 = \lceil r_1 \rceil$  \hspace{1cm}  \text{Round down reward}
3: Initialize $\tilde{A}(0, p) = \tilde{A}_0(p) = \begin{cases} 0 & p = 0, \\ -\infty & p > 0. \end{cases}$
4: for $t = 1, \ldots, T$ do
5: \quad Run Algorithm 2 with $I_L = I_L(t), \Delta c = c_t - c_{t-1}$, and $\tilde{A}(p) = \tilde{A}_{t-1}(p)$ for all $p = \{0, 1, \ldots, \left\lceil \frac{16T}{c_\delta} \right\rceil \} \cdot \kappa$, and obtain $\tilde{A}_t(p) := \tilde{A}(I_L, p)$ for all $p$.
6: \quad Run Algorithm 3 with $I_S = I_S(t)$ and $\tilde{A}(p) = \tilde{A}(I_L(t), p)$ for all $p = \{0, 1, \ldots, \left\lceil \frac{16T}{c_\delta} \right\rceil \} \cdot \kappa$, and obtain $\tilde{A}_t(p) := \tilde{A}(p)$ for all $p$.
7: end for

Algorithm 5 FPTAS for MPBKP-S in $\mathcal{O}(Tn \log \frac{n}{\epsilon^2})$

1: $P_0 \leftarrow P^\star$  
2: $p^* \leftarrow 0$
3: while $p^* < (1 - \epsilon)P_0$ do
4: \quad $P_0 \leftarrow \frac{P_0}{2}$
5: \quad Run Algorithm 4 with the current $P_0$.
6: \quad $p^* \leftarrow \max_{\{p \in \{0, \ldots, \left\lceil \frac{16T}{c_\delta} \right\rceil \} \cdot \kappa\} \cap \{p_{\tilde{A}_t(p)}> -\infty\}} p$
7: end while

Our main theorem for the approximation ratio for MPBKP follows.

Theorem 4 (Partially restating Theorem 2). Algorithm 5 is a fully polynomial approximation scheme for the MPBKP-S, which achieves $(1 + \epsilon)$ approximation ratio with running time $\mathcal{O} \left( \frac{Tn \log n}{\epsilon^2} \right)$.

5 A greedy algorithm for a special case of MPBKP-SS

In this subsection, we consider the special case of MPBKP-SS when all items have the same size, i.e., $q_i = q, \forall i \in [n]$. We again only present for the case $B_t = B, \forall t \in [T]$. We note that in the deterministic problems (MPBK or MPBKP-S), when items all have the same size, greedily adding items one by one in decreasing order of their rewards leads to the optimal solution. For MPBKP-SS, as the capacities are now stochastic, we wonder if there is any greedy algorithm performs well. We propose Algorithm 6, where we start with an empty set, and greedily insert the item that brings the maximum increment on expected profit, and we stop if adding any of the remaining items does not increase the expected profit.

Let $S^* \in \text{arg max}_{S \subseteq [n]} P(S) := R(S) - B \cdot \Phi(S)$, where

$$
\Phi(S) := \mathbb{E} \left\{ \sum_{t=1}^{T} \left[ \sum_{j \in I(t) \cap S} q_j - \max_{0 \leq t' < t} \left\{ c_t - c_{t'} - \sum_{j \in S : t' + 1 \leq j \leq t-1} q_j \right\} \right] \right\}^+ \right\}
$$

is the expected quantity of overflow on set $S$, and let $S_p$ be the set output by Algorithm 6. Then, we have the
Algorithm 6 Greedy algorithm according to profit change

1: \( S \leftarrow \emptyset \)
2: \( s \leftarrow 1 \)
3: while \( s == 1 \) do
4: \( i^* \leftarrow \arg \max_{i \in S} \{ \mathcal{P}(S \cup \{i\}) - \mathcal{P}(S) \} \)
5: if \( \mathcal{P}(S \cup \{i^*\}) - \mathcal{P}(S) \geq 0 \) then
6: \( S \leftarrow S \cup \{i^*\} \)
7: else
8: \( s \leftarrow 0 \)
9: end if
10: end while
11: \( S_p \leftarrow S \)
12: Return \( S_p \)

following theorem.

Theorem 5 (Restating Theorem 3). Algorithm 6 achieves 2-approximation factor for MPBKP-SS when items have the same size, i.e., \( \mathcal{P}(S_p) \geq \frac{1}{2} \mathcal{P}(S^*) \) in \( \mathcal{O}(n^2T|\Omega|) \).

The proof of the 2-approximation could be more nontrivial than one may think. The idea is to look at the greedy solution set \( S_p \) and the optimal solution set \( S^* \), where we will use the dual to characterize the optimal solution on each sample path. By swapping each item in \( S_p \) to \( S^* \) in replacement of the same item or two other items, we construct a sequence of partial solutions of the greedy algorithm as well as modified optimal solution set, while maintaining the invariant that the profit of \( S^* \) is bounded by the sum of two times the profit of items in \( S_p \) swapped into \( S^* \) so far and the additional profit of remaining items in the modified optimal solution set. We leave the formal proof of Theorem 5 to Appendix A.3.

6 Comments and Future Directions

The current work represents to the best of our knowledge the first FPTAS for the two multi-period variants of the classical knapsack problem. For MPBKP, we obtained the runtime \( \tilde{O} \left( n + \left( T^{3.25}/\epsilon^{2.25} \right) \right) \). This was done via the function approximation approach, where a function is approximated for each period. The runtime increases in \( T \) since we conduct \( T \) number of rounding downs, one after each \((\max, +)\)-convolution. An alternative algorithm with runtime \( \tilde{O} \left( n + \frac{T^2}{\epsilon^2} \right) \) is also provided in Appendix B. Note that the function we approximated is in the same form as used in the 0-1 knapsack problem (Chan, 2018). It is thus interesting to ask if we could instead directly approximate the following function:

\[
 f_T(c) = \max_x \left\{ \sum_{i \in I} r_i x_i : \sum_{i \in \bigcup_{t=1}^T I(t')} q_i x_i \leq c_t, \forall t \in [T], x \in \{0, 1\}^n \right\},
\]

where \( I = \bigcup_{t=1}^T I(t) \) and \( c = \{c_1, \ldots, c_T\} \) is a \( T \)-dimensional vector. Here we impose all \( T \) constraints in the function. The hope is that, if the above function could be approximated, and if we could properly define the \((\max, +)\)-convolution on \( T \) dimensional vectors (and have a fairly easy computation of it), then we may get an algorithm that depends more mildly on \( T \).

For MPBKP-S and MPBKP-SS, there seems to be less we can do without further assumptions. One direction to explore is parameterized approximation schemes: assuming that in the optimal solution, the total (expected)
penalty is at most $\beta$ fraction of the total reward. Then we may just focus on rewards. Our ongoing work suggests that an approximation factor of $\left(1 + \frac{1}{1-\beta}\right)$ may be achieved in $\tilde{O} \left(n + \left(T^{3.25}/\varepsilon^{2.25}\right)\right)$ for MPBKPS, and the same approximation factor in $\tilde{O} \left(n + \frac{1}{\varepsilon^2}\right)$ for MPBKPS.

We further note that the objective function for the three multiperiod variants are in fact submodular (but not non-negative, or monotone). Whether we can get a constant competitive solution in time $\tilde{O}(n)$, using approaches in submodular function maximization, is also an intriguing open problem.

Finally, motivated by applications, one natural extension that the authors are working on now is when there is a general non-decreasing cost function $\phi_t(\Delta c)$ for procuring capacity $\Delta c$ at time $t$, and the goal is to admit a profit maximizing set of items when the unused capacity can be carried forward. Another extension is when there is a bound on the leftover capacity that can be carried forward.

A Omitted Proofs

A.1 Proofs for Section 3

Proof of Proposition 1. We show that the solution corresponding to $f_T(c)$ is optimal for $c_T = c$ among all solutions feasible to (1). We prove by induction on $T$. Base case is $T = 1$, this reduces to 0-1 Knapsack problem,
and by definition, the solution corresponding to \( f_{\mathcal{I}(1)}(c) \) is the optimal feasible solution when the Knapsack capacity is \( c \). For the induction step, assume that the solution of \( f_{T-1}(c') \) is the optimal feasible solution to (1) for the \( T - 1 \) period problem and \( c_{T-1} = c' \), we show that the solution corresponding to \( f_T(c) \) is also the optimal feasible solution to (1) for the \( T \) period problem and \( c_T = c \).

By definition,

\[
f_T(c) = (f_{T-1} \oplus f_{\mathcal{I}(T)}(c))^{c_T} = \left( \max_{c' \in \mathbb{R}} (f_{T-1}(c') + f_{\mathcal{I}(T)}(c - c')) \right)^c.
\]

We first show that \( f_T(c) \) is at least the optimal value of (1) when \( c_T = c \). Suppose that, in the optimal solution of (1), the total size of accepted items up to time \( T - 1 \) is \( \hat{c} \) with \( \hat{c} < c \), then the optimal value is \( f_{T-1}(\hat{c}) + f_{\mathcal{I}(T)}(c - \hat{c}) \) since \( f_{T-1}(\hat{c}) \) is the maximum achievable reward with \( c_{T-1} = \hat{c} \) (by induction assumption) and \( f_{\mathcal{I}(T)}(c - \hat{c}) \) is the maximum achievable reward using items from \( \mathcal{I}(T) \) with space constraint \( c - \hat{c} \). Thus, we have that the optimal value \( f_{T-1}(\hat{c}) + f_{\mathcal{I}(T)}(c - \hat{c}) \leq (\max_{c' \in \mathbb{R}} (f_{T-1}(c') + f_{\mathcal{I}(T)}(c - c')))^c = f_T(c) \).

We next show the other direction: the optimal value of (1) for the \( T \) period problem with \( c_T = c \) is at least \( f_T(c) \). It suffices to show that every possible solution considered in \( f_T(c) \) satisfies the feasibility constraints in (1). By induction assumption, every solution of \( f_{T-1}(c') \) satisfies the constraints up to time \( T - 1 \). When computing \( f_T(c) \), we note that since \( f_{T-1}(c') \) is a function truncated at \( c_{T-1} \), which implies that \( f_{T-1}(c') = -\infty \) for any \( c' > c_{T-1} \). Therefore, any \( c' > c_{T-1} \) must not be in the solution of \( \max_{c' \in \mathbb{R}} (f_{T-1}(c') + f_{\mathcal{I}(T)}(c - c')) \). As a result, every solution of \( f_T(c) \) is enforcing that \( c' \leq c_{T-1} \), and satisfies the feasibility constraints up to time \( T \).

Combining both directions, we conclude the induction step, and thus the proof of the proposition.

---

**Proof of Lemma 2.** By the construction of \( \tilde{f}_t \), it should be clear that \( \tilde{f}_t \leq f_t \). We prove that \( (1 + \epsilon)^t \tilde{f}_t \geq f_t \) by induction on \( t \). Base case is when \( t = 1 \), we have that \( (1 + \epsilon)\tilde{f}_1 = (1 + \epsilon)f_{\mathcal{I}(1)}^{c_{\mathcal{I}(1)}} = f_1 \), where the inequality follows from Lemma 1. As for the induction step, assume that \( (1 + \epsilon)^{t-1} \tilde{f}_{t-1} \geq f_{t-1} \), we show that \( (1 + \epsilon)^t \tilde{f}_t \geq f_t \). Again, by Lemma 1 we have that

\[
(1 + \epsilon)^{t-1} \tilde{f}_{t-1} \geq (1 + \epsilon)\tilde{f}_{t-1} \geq f_{t-1}.
\]

Combined with the induction hypothesis, we have that

\[
(1 + \epsilon)^{t-1} \left( \tilde{f}_{t-1} \oplus \tilde{f}_{\mathcal{I}(t)} \right) = \left( (1 + \epsilon)^{t-1} \tilde{f}_{t-1} \right) \oplus \left( (1 + \epsilon)^{t-1} \tilde{f}_{\mathcal{I}(t)} \right) \geq f_{t-1} \oplus f_{\mathcal{I}(t)}.
\]

Taking truncation on both sides, we have that

\[
(1 + \epsilon)^{t-1} \tilde{f}_t = (1 + \epsilon)^{t-1} \left( \tilde{f}_{t-1} \oplus \tilde{f}_{\mathcal{I}(t)} \right)^{c_t} \geq \left( f_{t-1} \oplus f_{\mathcal{I}(t)} \right)^{c_t} = f_t.
\]

Because of rounding down, we have that \( (1 + \epsilon)\tilde{f}_t \geq \tilde{f}_t \). Therefore,

\[
(1 + \epsilon)^t \tilde{f}_t \geq (1 + \epsilon)^{t-1} \tilde{f}_t \geq f_t.
\]

This concludes the induction step, and thus the proof of the lemma.
A.2 Proofs for Section 4

This section is devoted to the proof of Theorem 4. To proceed, we first present the following result on Algorithm 2.

Lemma 3. Given a set of partial solutions with leftover capacities \( \hat{A}(p) \) for all \( p \in \{0, 1, \ldots, \lceil 16T / \epsilon^2 \rceil : \kappa \) the additional capacity available for packing \( \Delta c \), and the set of large items to be added \( \mathcal{I}_L := \{1, \ldots, I_L\} \), the output of Algorithm 2, \( \hat{A}(I_L, p) \), satisfies:

\[
\hat{A}(I_L, p) = \max_{I', \bar{p}: I' \subseteq \mathcal{I}_L} \hat{A}(\bar{p}) + \Delta c - Q(I'), \quad \forall p.
\]

That is, \( \hat{A}(I_L, p) \) is the maximum leftover capacity for any solution with (rounded) profit at least \( p \) obtained by adding items in \( \mathcal{I}_L \) to the solutions corresponding to \( \hat{A}(\cdot) \).

Proof of Lemma 3. We will prove a more general result than (12), i.e.,

\[
\hat{A}(i, p) = \max_{I', \bar{p}: I' \subseteq \{1, \ldots, i\}} \hat{A}(\bar{p}) + \Delta c - Q(I'), \quad \forall p
\]

We prove this by induction. The base case \((i = 0)\) is vacuously true. Now we assume that (13) holds for all \( p \in \{0, 1, \ldots, \lceil 16T / \epsilon^2 \rceil \} \kappa \) and for all \( k \in [i - 1] \). Consider some \( p \in \{0, 1, \ldots, \lceil 16T / \epsilon^2 \rceil \} \kappa \), and let \( I^* \) be any set achieving the maximum in (13) so that \( \hat{P}(I^*) \geq p - \bar{p} \) for some \( \bar{p} \in \{0, 1, \ldots, \lceil 16T / \epsilon^2 \rceil \} \kappa \). We will show that \( \hat{A}(i, p) \) is at least the leftover capacity under solution \( I^* \) via case analysis:

- Case \( i \notin I^* \): In this case, the leftover capacity under \( I^* \) is the leftover capacity by \( d_i \), which is the sum of leftover capacity in \( I^* \) by \( d_{i-1} \) and \( c_d - c_{d_{i-1}} \). By induction hypothesis, \( \hat{A}(i - 1, p) \) is no less than the leftover capacity of \( I^* \) by \( d_{i-1} \), and therefore, by lines 4 and 8, \( \hat{A}(i, p) \geq \hat{A}(i - 1, p) + c_d - c_{d_{i-1}} \) which in turn is no less than the leftover capacity under \( I^* \) by \( d_i \). By optimality of \( I^* \), all the inequalities must be equalities.

- Case \( i \in I^* \): Let \( I' = I^* \setminus \{i\} \), and let \( p' = \hat{P}(I') \) be its rounded profit. Then by induction hypothesis, \( \hat{A}(i - 1, p') \) is no less than the leftover capacity under \( I' \) by \( d_{i-1} \). Further, by packing item \( i \) in the solution corresponding to \( \hat{A}(i - 1, p') \), the change in profit is larger than by packing item \( i \) in \( I' \) (the penalty is no less under \( I' \) since it has weakly smaller leftover capacity). Therefore, packing item \( i \) in the solution corresponding to \( \hat{A}(i - 1, p') \) gives a solution with at least as large a rounded profit as \( p \) and at least as much leftover capacity by \( d_i \) as \( I^* \). Therefore, in turn \( \hat{A}(i, p) \) is at least as much as the leftover capacity in \( I^* \). Since we assume \( I^* \) to have the largest leftover capacity with profit at least \( p \), all the inequalities must be equalities.

This completes the induction step, and thus the proof of the lemma.

Next, we have the following Lemma as a preparation for our result on \( \hat{A}(p) \) of Algorithm 3.
Lemma 4. Given some capacity $c$ and a set of small items $I_S$ with $p_{\text{max}} := \max_{i \in I_S} p_i$, let $S^*$ be the profit-optimal subset, i.e., $S^* = \arg \max_{S \subseteq I_S} \mathcal{P}(S) = \mathcal{R}(S) - B \left( Q(S) - c \right)^+$. Further, let $\tilde{I}_S := \{ i \in I_S \mid q_i \leq c \}$ and relabel the items in $\tilde{I}_S$ as $\{ 1', \ldots, |\tilde{I}_S|' \}$ (in decreasing order of reward density $r_i/q_i$). Let $i'$ be such that $\sum_{j'=1}^{i'} q_{j'} \leq c$ and $\sum_{j'=1}^{(i'+1)'} q_{j'} > c$. Then, the solution $S' := \{ 1', \ldots, i' \}$ satisfies

- $Q(S') \leq Q(S^*)$,
- $\mathcal{P}(S') \geq \mathcal{P}(S^*) - p_{\text{max}}$.

Proof of Lemma 4. The first item can be shown by contradiction. Suppose that to the contrary $Q(S') > Q(S^*)$, that is, $S'$ uses more space than $S^*$. Since the items in $S'$ have the highest reward densities, it is in fact the optimal solution which uses space $Q(S') < c$. Since the optimal profit is non-decreasing in the capacity $c$, this violates optimality of $S^*$.

To see the second item, we look at two different cases. First, if $S^* \cap \left( I_S \setminus \tilde{I}_S \right) \neq \emptyset$, i.e., the optimal packing $S^*$ includes some item $i^*$ with $q_{i^*} > c$, then there should be only one item in $S^*$, i.e., $S^* = \{ i^* \}$. In this case, $\mathcal{P}(S^*) = p_{i^*} = p_{\text{max}}$ and thus $\mathcal{P}(S') \geq \mathcal{P}(\emptyset) = 0 = \mathcal{P}(S^*) - p_{\text{max}}$.

Second, if $S^* \cap \left( I_S \setminus \tilde{I}_S \right) = \emptyset$, then $S^* = \arg \max_{S \subseteq I_S} \mathcal{P}(S)$. Note that $\mathcal{P}(S^*)$ is upper bounded by the reward for the fractional packing: $\mathcal{P}(S^*) \leq \mathcal{R}_{LP} := \mathcal{R}(S') + r_{(i+1)'} \cdot \frac{c - Q(S')}{q_{(i+1)'}} \leq \mathcal{R}(S') + r_{(i+1)'} = \mathcal{P}(S') + p_{(i+1)'} \leq \mathcal{P}(S^*) + p_{\text{max}}$.

In either cases, we conclude that $\mathcal{P}(S') \geq \mathcal{P}(S^*) - p_{\text{max}}$.

Before presenting our result on $A_t(p)$, we will need the following definitions. For a solution $S = S(1) \cup S(2) \cup \cdots \cup S(T)$ with $S(t) = S_L(t) \cup S_S(t)$, denoting the items with deadline $t$ in $S$, let the large items be indexed as $S_L(t) = \{ i_1^{(t)}, \ldots, i_{L_t}^{(t)} \}$ in the order in which Algorithm 2 considers them, and the small items be indexed arbitrarily $S_S(t) = \{ j_1^{(t)}, \ldots, j_{S_t}^{(t)} \}$. Let $S_L := S_L(1) \cup \cdots \cup S_L(T)$ and $S_S := S_S(1) \cup \cdots \cup S_S(T)$ denote the large and small items in $S$, respectively (this depends on the choice of $P_t$ but we suppress the dependence for brevity). We define the rounded profit of $S$ as:

$$
\hat{\mathcal{P}}(S) = \mathcal{R}(S_L) - \sum_{t=1}^{T} \sum_{k=1}^{L_t} B \left( \sum_{t' \leq k} q_{(t')} - \max_{0 \leq t' < t} \left\{ c_t - c_{t'} - \sum_{t'+1 \leq t'' < t} Q(S(\tau)) \right\} \right)^+ \left. \kappa \right| \kappa
+ \sum_{t=1}^{T} \mathcal{R}(S_S(t)) - B \left( Q(S(t)) - \max_{0 \leq t' < t} \left\{ c_t - c_{t'} - \sum_{t'+1 \leq t'' < t} Q(S(\tau)) \right\} \right)^+ \left. \kappa \right| \kappa.
$$

That is, we add the rounded rewards of the large items, and for small items, we first group the small items by their deadlines, and for each deadline we round the sum of unrounded rewards of small item. Further, let

$$
\hat{C}_t(p) := \max_{S \subseteq \bigcup_{t'=1}^{t'} I(t'): \hat{\mathcal{P}}(S) \geq p} \max_{0 \leq t' < t} \left\{ c_t - c_{t'} - \sum_{t'+1 \leq t'' \leq t} Q(S(\tau)) \right\}
$$

16
denote the feasible partial solution with largest leftover capacity at time $t$ and rounded total profit at least $p$. Then, we have the following lemma.

Lemma 5. For any $t = 1, \ldots, T$ and any $p' \in \{0, 1, \ldots, \left\lceil \frac{16t}{2\epsilon} \right\rceil \}$, we have that $\tilde{A}_t(p) \geq \tilde{C}_t(p')$ for some $p \geq p' - \frac{1}{2\epsilon^2} t P_0 t - \kappa t \geq p' - \frac{1}{2\epsilon}(1-\epsilon/4) P_0 t$. That is, for any rounded total profit $p'$ by time $t$, there exists some partial solution $\tilde{A}_t$ of Algorithm 4 which has at least as much leftover capacity at time $t$ the optimal solution $\tilde{C}_t(p')$, and has rounded profit $p$ not too much smaller than $p'$.

Proof of Lemma 5. We prove by induction on $t$. Base case is when $t = 1$. Let $S'$ be the solution corresponding to $\tilde{C}_1(p')$, i.e., $S' := \arg \max \{ \{ S \subseteq T(1) \} : c_1 - Q(S) \}$, and let $S'_L = S' \cap I_L$, $S'_S = S' \cap I_S$. Then $\tilde{P}(S'_L) = \hat{P}(S'_L)$. By Lemma 3, $\hat{A}(I_L(1), \hat{P}(S'_L))$ is the maximum leftover capacity using items in $I_L(1)$ earning rounded profit $\hat{P}(S'_L)$. Thus, $\tilde{A}_1(\tilde{P}(S'_L)) = \hat{A}(I_L(1), \hat{P}(S'_L)) \geq c_1 - Q(S'_L)$. Let $S''_L$ be the solution corresponding to $\hat{A}_1(\hat{P}(S'_L))$, and thus $Q(S''_L) \leq Q(S'_L)$. Consider appending the partial solution $S''_L$ using items from $I_S(1)$. Let $S''_S$ be the small item set obtained by adding small items greedily in their reward densities, subject to the constraint that $Q(S''_L) \leq Q(S''_S)$. Then, by Lemma 4, with $S''_S$ being the greedy solution, $Q(S''_S)$ being the capacity constraint and $S''_S$ being the optimal filling of small items in $I_S(1)$, we conclude that

$$\mathcal{P}(S''_S) \geq \mathcal{P}(S'_S) - \frac{1}{2T} \epsilon P_0.$$ 

Therefore, $p' = \hat{P}(S') = \hat{P}(S'_L \cup S'_S) = \hat{P}(S'_L) + \Delta \hat{P}(S'_S, c_1 - Q(S'_L)) \leq \hat{P}(S''_L) + \Delta \hat{P}(S''_S, c_1 - Q(S'_L)) + \frac{1}{2T} \epsilon P_0 + \kappa \leq \hat{P}(S''_L) + \Delta \hat{P}(S''_S, c_1 - Q(S''_L)) + \frac{1}{2T} \epsilon P_0 + \kappa = \hat{P}(S''_L \cup S''_S) + \frac{1}{2T} \epsilon P_0 + \kappa$. Let $p = \hat{P}(S''_L \cup S''_S)$. From Algorithm 3, we know that since $S''_S$ includes the small items in $I_S(1)$ with the highest reward densities, the solution $S''_L \cup S''_S$ is one feasible solution for $\hat{A}_1(p)$. We thus have that

$$\tilde{A}_1(p) \geq c_1 - Q(S''_L \cup S''_S) \geq c_1 - Q(S') = \tilde{C}_1(p'),$$

where $p \geq p' - \frac{1}{2T} \epsilon P_0 - \kappa$, and the second inequality follows from the facts that $Q(S''_L) \leq Q(S'_L)$ and $Q(S''_S) \leq Q(S''_S)$.

For the induction step, assume that for all $p'' \in \{0, 1, \ldots, \left\lceil \frac{16t}{2\epsilon^2} \right\rceil \}$, we have that $\tilde{A}_{t-1}(p) \geq \tilde{C}_{t-1}(p'')$ for some $p \geq p'' - \frac{1}{2T} \epsilon P_0 (t-1) - \kappa (t-1)$. We want to show that for all $p', \tilde{A}_t(p) \geq \tilde{C}_t(p')$ for some $p \geq p' - \frac{1}{2T} \epsilon P_0 t - \kappa t$. Let $S'$ be the solution corresponding to $\tilde{C}_t(p')$, i.e.,

$$S' := \arg \max \{ S \subseteq \bigcup_{t'=1}^{t-1} I(t') \in \mathcal{P}(S) \geq p' \} \max \left\{ c_t - c_{t'} - \sum_{t'+1 \leq t \leq t} Q(S(\tau)) \right\},$$

and let $S'_L = S' \cap I_L$, $S'_S = S' \cap I_S$. Let $S'(t) := \{ i \in S' \mid d_i = t \}$ and consider the partial solution $\bigcup_{t'=1}^{t-1} S''(t')$. By induction assumption, there exists some partial solution $\bigcup_{t'=1}^{t-1} S''(t')$ such that $Q\left(\bigcup_{t'=1}^{t-1} S''(t')\right) \leq Q\left(\bigcup_{t'=1}^{t-1} S'(t')\right)$, and that $\hat{P}\left(\bigcup_{t'=1}^{t-1} S''(t')\right) \geq \hat{P}\left(\bigcup_{t'=1}^{t-1} S'(t')\right) - \frac{1}{2T} \epsilon P_0 (t-1) - \kappa (t-1)$. First, we fill the partial solution $\bigcup_{t'=1}^{t-1} S''(t')$ using items from $I_L(t)$ according to Algorithm 2. Note that one feasible solution is $S''_L(t)$ which results in $\bigcup_{t'=1}^{t-1} S''(t') \cup S''_L(t)$. This keeps $Q\left(\bigcup_{t'=1}^{t-1} S''(t') \cup S''_L(t)\right) \leq Q\left(\bigcup_{t'=1}^{t-1} S'(t') \cup S'_L(t)\right)$ while having $\hat{P}\left(\bigcup_{t'=1}^{t-1} S''(t') \cup S''_L(t)\right) \geq \hat{P}\left(\bigcup_{t'=1}^{t-1} S'(t') \cup S'_L(t)\right) - \frac{1}{2T} \epsilon P_0 (t-1) - \kappa (t-1)$. Suppose that after filling items from $I_L(t)$ using DP in Algorithm 2, the resulting set corresponding to
\[ \hat{A}_t \left( \tilde{\mathcal{P}} \left( \bigcup_{t'=1}^{t-1} S''(t') \cup S'_L(t) \right) \right) \text{ is } \tilde{S}, \text{ then this } \tilde{S} \text{ would only use less space and earn more profit, i.e.,} \]

\[
\begin{align*}
Q \left( \tilde{S} \right) & \leq Q \left( \bigcup_{t'=1}^{t-1} S''(t') \cup S'_L(t) \right) \\
\tilde{\mathcal{P}} \left( \tilde{S} \right) & \geq \tilde{\mathcal{P}} \left( \bigcup_{t'=1}^{t-1} S''(t') \cup S'_L(t) \right) \\
& \geq \tilde{\mathcal{P}} \left( \bigcup_{t'=1}^{t-1} S''(t') \cup S'_L(t) \right) - \frac{1}{2T} \epsilon P_0 (t - 1) - \kappa (t - 1).
\end{align*}
\]

Next, consider filling the partial solution \( \tilde{S} \) using items from \( \mathcal{I}_S(t) \). Let \( S''_S(t) \) be the small item set obtained by adding small items greedily in their reward densities, subject to the constraint that \( Q (S''_S(t)) \leq Q (S'_S(t)) \). Then, by Lemma 4, with \( S''_S(t) \) being the greedy solution, \( Q(S''_S(t)) \) being the capacity constraint and \( S'_S(t) \) being the optimal filling of small items in \( \mathcal{I}_S(t) \), we conclude that

\[ \mathcal{P}(S''_S(t)) \geq \mathcal{P}(S'_S(t)) - \frac{1}{2T} \epsilon P_0. \]

Therefore,

\[
\begin{align*}
p' &= \tilde{\mathcal{P}}(S') = \tilde{\mathcal{P}} \left( \bigcup_{t'=1}^{t-1} S'(t') \cup S'_L(t) \cup S'_S(t) \right) \\
& \leq \tilde{\mathcal{P}} \left( \tilde{S} \cup S''_S(t) \right) + \frac{1}{2T} \epsilon P_0 (t - 1) + \kappa (t - 1) + \frac{1}{2T} \epsilon P_0 + \kappa \\
& \leq \tilde{\mathcal{P}} \left( \tilde{S} \cup S''_S(t) \right) + \frac{1}{2T} \epsilon P_0 t + \kappa t.
\end{align*}
\]

Let \( p = \tilde{\mathcal{P}} \left( \tilde{S} \cup S''_S(t) \right) \). From Algorithm 3, we know that since \( S''_S(t) \) includes the small items in \( \tilde{S}_S(t) \) with the highest reward densities, the solution \( \tilde{S} \cup S''_S(t) \) is one feasible solution for \( \tilde{A}_t(p) \). We thus have that

\[
\begin{align*}
\tilde{A}_t(p) & \geq \max_{0 \leq t' < t} \left\{ c_t - c_{t'} - \sum_{t'+1 \leq \tau \leq t} Q \left( \left( \tilde{S} \cup S''_S(t) \right) (\tau) \right) \right\} \\
& \geq \max_{0 \leq t' < t} \left\{ c_t - c_{t'} - \sum_{t'+1 \leq \tau \leq t} Q(S'(\tau)) \right\} = \tilde{C}_t(p'),
\end{align*}
\]

where \( p \geq p' - \frac{1}{2T} \epsilon P_0 t - \kappa t \). This finishes the induction step, and thus the proof of the lemma. \( \blacksquare \)

Using the above lemmas, we prove the following approximation result.

**Proposition 3.** Let \( S' \) denote the optimal solution set by Algorithm 4, i.e., \( S' \) is the solution set corresponding to \( A_T(p^*) \) where \( p^* \) is the maximum \( p \) such that \( A_T(p) > -\infty \). Let \( S^* \) be the optimal solution set to the original MPBKP-S. Then,

\[ \mathcal{P}(S') \geq p^* \geq (1 - \epsilon - 3e^2 / 8) \mathcal{P}(S^*). \]
Proof. Note that $\tilde{\mathcal{P}}(S') = p^*$. Lemma 5 implies that
\[
\tilde{A}_T(p^*) \geq \tilde{C}_T \left( p^* + \frac{1}{2T} \epsilon P_0 + \kappa T \right) = \tilde{C}_T \left( p^* + \frac{1}{2} \epsilon P_0 + \kappa T \right).
\]
Since $\tilde{C}_T(\tilde{\mathcal{P}}(S^*)) > -\infty$, we have that $\tilde{A}_T \left( \tilde{\mathcal{P}}(S^*) - \frac{1}{2} \epsilon P_0 - \kappa T \right) \geq \tilde{C}_T(\tilde{\mathcal{P}}(S^*)) > -\infty$. Therefore,
\[
\mathcal{P}(S') \geq p^* \geq \tilde{\mathcal{P}}(S^*) - \frac{1}{2} \epsilon P_0 - \kappa T.
\]
By the definition of $\tilde{\mathcal{P}}$ as in (14), for each large item, the reward is rounded down by at most $\kappa$ and the penalty is rounded up by at most $\kappa T$. Note that each large items earns profit $p_i$ unless it is paying more penalty than it would be by itself, which happens at most once at each period. Thus, there are at most $\frac{2P_0}{\epsilon} + T = \frac{4T}{\epsilon} + T$ number of large items, and thus the total number of rounding downs (for both large and small items) is bounded by $\frac{4T}{\epsilon} + 2T$. Therefore, we have that $\mathcal{P}(S^*) \leq \tilde{\mathcal{P}}(S^*) + (\frac{4T}{\epsilon} + 2T) \kappa$. In conclusion,
\[
\mathcal{P}(S') \geq p^* \geq \tilde{\mathcal{P}}(S^*) - \frac{1}{2} \epsilon P_0 - \kappa T
\geq \mathcal{P}(S^*) - \left( \frac{4T}{\epsilon} + 2T \right) \kappa - \frac{1}{2} \epsilon P_0 - T \kappa = \mathcal{P}(S^*) - \epsilon P_0 - 3T \kappa
\geq (1 - \epsilon - 3 \epsilon^2 / 8) \mathcal{P}(S^*).
\]

It remains to validate Algorithm 5 in the search of $P_0$ which satisfies (10). When Algorithm 5 terminates, it returns the last $p^*$ and the solution set $S'$ corresponding to $\tilde{A}_T(p^*)$. We then have the following lemmas.

**Lemma 6.** Algorithm 5 terminates within $\log n$ iterations of the "while" loop (line 3).

**Proof of Lemma 6.** When $P_0$ satisfies (10), by Proposition 3 we have that
\[
p^* \geq (1 - \epsilon)\mathcal{P}(S^*) \geq (1 - \epsilon)P_0.
\]
Thus, the "while" loop terminates when $P_0$ satisfies (10), if not before $P_0$ satisfies (10). When $P_0$ satisfies (10), we would also have $\mathcal{P}(S^*)/2 \leq P_0 \leq \mathcal{P}(S^*)$. Therefore, the number of iterations is upper bounded by
\[
\text{number of iterations} \leq \log \frac{\bar{P}/2}{\mathcal{P}(S^*)/2} \leq \log n,
\]
where we have used the fact that $\bar{P} \leq nP \leq n\mathcal{P}(S^*)$. □

**Lemma 7.** After running Algorithm 5, suppose $S'$ is the solution set corresponding to $\tilde{A}_T(p^*)$, and $S^*$ is the optimal solution set to the original MPBKP-S. Then,
\[
\mathcal{P}(S') \geq (1 - \epsilon)\mathcal{P}(S^*).
\]
Proof of Lemma 7. If the “while” loop terminates when \( P_0 > \mathcal{P}(S^*) \), i.e., it stops before \( P_0 \) falls below \( \mathcal{P}(S^*) \), then we have that 
\[
\mathcal{P}(S') \geq p^* \geq (1 - \epsilon)P_0 > (1 - \epsilon)\mathcal{P}(S^*).
\]
Otherwise, from the proof of Lemma 6 we know that the “while” loop must terminate when \( P_0 \) first falls below \( \mathcal{P}(S^*) \), which implies that the last \( P_0 \) satisfies (10). Then by Proposition 3 we again have that 
\[
\mathcal{P}(S') \geq (1 - \epsilon)\mathcal{P}(S^*).
\]
In either case, the solution we obtained from Algorithm 5 achieves \((1 - \epsilon)\) optimal. ■

With the above Lemmas, we are in a position to prove Theorem 4.

Proof of Theorem 4. By Lemma 7, the solution found is within \((1 - \epsilon)\) factor of \( \mathcal{P}(S^*) \). Since the running time of the algorithm is \( O(n \cdot \lceil \frac{16T}{\epsilon^2} \rceil \cdot \log n) = O\left(\frac{Tn \log n}{\epsilon^2}\right) \), which is polynomial in \( n \) and \( 1/\epsilon \), the theorem follows. ■

A.3 Proof of Theorem 5

This subsection is devoted to the proof of Theorem 5. The idea is to look at the greedy solution set \( S_p \) and the optimal solution set \( S^* \), and by swapping each item in \( S_p \) to \( S^* \) in replacement of the same item or two other items, we construct a sequence of partial solutions of the greedy algorithm as well as modified optimal solution set, while maintaining the invariant that the profit of \( S^* \) is bounded by the sum of two times the profit of items in \( S_p \) swapped into \( S^* \) so far and the additional profit of remaining items in the modified optimal solution set. We will make this clear in the following.

To proceed, we first introduce some notations. Let \( S_p = \{g_1, \ldots, g_l\} \) and \( S^* = \{o_1, \ldots, o_m\} \), i.e., the items in greedy solution is denoted by \( g_i \)'s and the items in the optimal solution is denoted by \( o_i \)'s. Further, for any two sets of items \( S_1 \) and \( S_2 \), we define the incremental profit of adding \( S_2 \) to the set \( S_1 \) as 
\[
\Delta \mathcal{P}(S_1, S_2) = \mathcal{P}(S_1 \cup S_2) - \mathcal{P}(S_1).
\]
Recall that \( \Phi(S) \) is the expected number of units of overflows that penalties are paid, which will be referred as overflow units in the following. The incremental expected overflow units of adding \( S_2 \) to the set \( S_1 \) is defined as 
\[
\Delta \Phi(S_1, S_2) = \Phi(S_1 \cup S_2) - \Phi(S_1).
\]
On a sample path of incremental capacities \( \omega = \{c_t\}_{t=1}^T \), let \( a_t := c_t - c_{t-1} \). Let \( \mathcal{P}_\omega \) and \( \Phi_\omega \) be the profit and overflow units function, respectively, and the incremental profit of adding \( S_2 \) to the set \( S_1 \) is 
\[
\Delta \mathcal{P}_\omega(S_1, S_2) = \mathcal{P}_\omega(S_1 \cup S_2) - \mathcal{P}_\omega(S_1).
\]
Similarly, on sample path \( \omega \), the incremental penalty of adding \( S_2 \) to the set \( S_1 \) is 
\[
\Delta \Phi_\omega(S_1, S_2) = \Phi_\omega(S_1 \cup S_2) - \Phi_\omega(S_1).
\]
Then, the relationship of $\Delta P$ and $\Delta \Phi$ is:

\[
\Delta P(S_1, S_2) = P(S_1 \cup S_2) - P(S_1) = R(S_1 \cup S_2) - R(S_1) - B \cdot \Phi(S_1 \cup S_2) + B \cdot \Phi(S_1) \\
= R(S_2) - B \cdot \Delta \Phi(S_1, S_2).
\]

Similarly, on a sample path, we have that $\Delta P_\omega(S_1, S_2) = R(S_2) - B \cdot \Delta \Phi_\omega(S_1, S_2)$.

Let $\mathcal{S}(t) := \{j \in S \mid d_j = t\}$. Given a (partial) solution $\mathcal{S}$ and a sample path of capacities $\omega = \{c_t\}_{t=1}^T \in \Omega$. We let $a_t := c_t - c_{t-1}$, and the available leftover capacity at time $t$ (after including items in $\mathcal{S}(t)$) is

\[
\max \left\{ \sup_{t' \leq t} \sum_{\tau = t'}^t a_\tau - Q(S(\tau)), 0 \right\} := C_\omega^S(t).
\]

Then, overflow units at time $t$ is

\[
\max \left\{ \sup_{t' \leq t} Q(S(\tau)) - \sum_{\tau = t'}^t a_\tau, 0 \right\} := \Phi^S_\omega(t),
\]

and the total overflow units is $\Phi_\omega(S) = \sum_{t=1}^T \Phi^S_\omega(t)$.

With the above definitions, we first consider the calculation of overflows on a set $\mathcal{S}$ of items for a given sample path $\omega$. This is done in Algorithm 7.

**Algorithm 7 OVERFLOW ASSIGNMENT**

1: **Parameters**: Sample path of capacities $(c_1, \ldots, c_T) \in \mathbb{N}^T$, an arbitrary ordered list of requests $L = (d_1, d_2, \ldots, d_n)$
2: **Initialize**: Remaining capacity $a^\tau = (a_1^\tau, \ldots, a_T^\tau) \leftarrow (a_1, \ldots, a_T)$ $\triangleright a_t = c_t - c_{t-1}$
3: **Initialize**: Units of overflow needing to pay penalty $\Phi \leftarrow 0$
4: $i \leftarrow 1$
5: **while** $i \leq n$ **do**
6: \hspace{1em} $q^\prime \leftarrow q_i$
7: \hspace{1em} $t_i = \max\{t \leq d_i : a_t^\tau > 0\}$
8: \hspace{1em} **while** $q^\prime > 0$ **do**
9: \hspace{2em} **if** $t_i < \infty$ and $t_i > 0$ **then**
10: \hspace{3em} $a_t^\tau \leftarrow a_t^\tau - \min\{a_t^\tau, q^\prime\}$
11: \hspace{3em} $q^\prime \leftarrow q^\prime - \min\{a_t^\tau, q^\prime\}$
12: \hspace{3em} $t_i \leftarrow t_i - 1$
13: \hspace{2em} **else**
14: \hspace{3em} $\Phi \leftarrow \Phi + q^\prime$
15: \hspace{3em} $q^\prime \leftarrow 0$
16: \hspace{1em} **end if**
17: **end while**
18: $i \leftarrow i + 1$
19: **end while**
20: **Return** $(a^\tau, \Phi)$

Algorithm 7 serves dual purpose – while calculating the overflow, it also implicitly finds an assignment of the items which do not suffer a penalty to supply units. The assignment of items to supply units can be non-unique, while Algorithm 7 identifies one way of matching. Intuitively, the algorithm assigns items to the latest available units, saving the earlier capacity for items with shorter deadlines. This allows us to find the total overflows by considering the items in an arbitrary order (instead of in increasing order of deadlines), which is in turn useful for finding incremental profit $\Delta P$ when we add a set of requests to an existing set of accepted requests. We begin
with the following lemma which proves that Algorithm 7 indeed finds the minimum overflow.

**Lemma 8.** Given a sample path \( \omega \in \mathbb{N}^T \) of supply, and a set \( S \) of items with general integer demands, let \( \mathcal{L} = (d_1, \ldots, d_n) \) be an arbitrary ordering of the items in \( S \) (\( d_i \) denoting the deadlines). Then the overflow units \( \Phi \) returned when executing Algorithm 7 (OVERFLOW ASSIGNMENT) on \((\omega, \mathcal{L})\) satisfies \( \Phi = \Phi_\omega(S) \).

**Proof of Lemma 8.** We will use LP duality to prove the Lemma. In a nutshell, we will use the assignment created by Algorithm 7 to create a feasible solution to the dual LP such that the objective function of the dual matches the objective function penalty of the assignment. Since any feasible solution of the dual lower bounds the optimal, we would have thus demonstrated the optimality of the assignment and hence of the overflow units \( \Phi \).

\[
\begin{align*}
\text{(PRIMAL)} & \quad \min \sum_{i=1}^n y_i \\
\text{s.t.} & \quad \forall t \in [T] : \quad -\sum_{i : d_i \leq t} x_i \geq -c_t \\
& \quad \forall i \in [n] : \quad x_i + y_i = q_i \\
& \quad x_i, y_i \geq 0
\end{align*}
\]

\[
\begin{align*}
\text{(DUAL)} & \quad \max \sum_{i=1}^n q_i \gamma_i - \sum_t \lambda_t c_t \\
\text{s.t.} & \quad \forall i \in [n] : \quad \gamma_i \leq 1 \\
& \quad \forall i \in [n] : \quad \gamma_i \leq \sum_{t \geq d_i} \lambda_t \\
& \quad \lambda_t \geq 0
\end{align*}
\]

To construct the dual solution, let \( \tau = \min\{t : a^*_t > 0\} \). That is, \( \tau \) is the first time at which there is some capacity remaining after the assignment of OVERFLOW ASSIGNMENT. By the nature of the algorithm, there are no items with \( d_i \geq \tau \) for which penalty is paid, and in fact all items with \( d_i \geq \tau \) are served with capacity that arrives before time \( \tau \) or later. Therefore, the overflow units under the assignment is the total size of items with \( d_i < \tau \) minus the capacity \( c_{\tau-1} \) (since this capacity is only used by requests with \( d_i < \tau \)).

Now construct a dual solution as follows:

\[
\lambda_t = \begin{cases} 
1 & t = \tau - 1, \\
0 & t \neq \tau - 1;
\end{cases} \quad \gamma_i = \begin{cases} 
1 & d_i \leq \tau - 1, \\
0 & d_i \geq \tau.
\end{cases}
\]

It is easy to verify that this is a feasible dual solution. Further, the objective function value under this feasible dual is

\[
\sum_{i : d_i \leq \tau - 1} q_i - c_{\tau-1}
\]

which is exactly the overflow units of the primal assignment. Therefore, the primal solution in fact attains the optimal objective. \( \blacksquare \)

As a result of Algorithm 7 and Lemma 8, we have the following lemma.

**Lemma 9.** Let \( S \) be a set of items disjoint with \( S_1 \) and \( S_2 \). If for some \( \omega = \{c_t \mid t \in [T]\} \in \Omega \), we have \( C^S_\omega(t) \geq C^S_\omega(t), \forall t \in [T] \), then, \( \Delta \mathcal{P}_\omega(S_1, S) \geq \Delta \mathcal{P}_\omega(S_2, S) \). If this is true for all \( \omega \in \Omega \), we further have that \( \Delta \mathcal{P}(S_1, S) \geq \Delta \mathcal{P}(S_2, S) \).

**Proof of Lemma 9.** It suffices to show that \( \Delta \Phi_\omega(S_1, S) \leq \Delta \Phi(S_2, S) \). Note that

\[
\Delta \Phi_\omega(S_1, S) = \Phi_{\omega'}(S), \text{ where } \omega' = \{C^S_\omega(t) \mid t \in [T]\},
\]

22
\[ \Delta \Phi_\omega(S_2, S) = \Phi_{\omega''}(S), \text{ where } \omega'' = \left\{ C^S_\omega(t) \mid t \in [T] \right\}. \]

By Lemma 8, the ordering of items in \( S \) does not matter when computing the total overflow units, and we may apply Algorithm 7 to compute \( \Phi_{\omega'}(S) \) and \( \Phi_{\omega''}(S) \). Since \( C^S_\omega(t) \geq C^S_\omega(t), \forall t \in [T] \), as we apply Algorithm 7, for any capacity in \( \omega'' \) that is used to serve a unit of demand in \( S \), we have the same capacity in \( \omega' \) that can be used to serve the same unit of demand in \( S \). It then follows that \( \Phi_{\omega'}(S) \leq \Phi_{\omega''}(S) \), which implies that \( \Delta \Phi_\omega(S_1, S) \leq \Delta \Phi_\omega(S_2, S) \).

We next show the submodularity of \( \mathcal{P} \).

**Lemma 10.** For any \( S_1 \subseteq S_2 \), we have that \( \Delta \mathcal{P}(S_1, S_3) \geq \Delta \mathcal{P}(S_2, S_3) \).

**Proof of Lemma 10.** Since \( S_1 \subseteq S_2 \), in each realized sample path of capacities \( \omega = \{c_t\}_{t=1}^T \), it should be clear that \( C^S_\omega(t) \geq C^S_\omega(t), \forall t, \) i.e., at each time period, the available remaining capacity on \( S_1 \) is no less than the available remaining capacity on \( S_2 \). Thus, by Lemma 9, the result follows.

Lemma 9 and Lemma 10 showed the relationship of incremental profit change of adding a set of items on top of two other sets of items. Specifically, if one set always has more remaining capacity than the other set, then adding a third set to one generates more incremental profit than adding the same set to the other.

For the rest of this section, we impose the assumption that \( q_i = q, \forall i \in [N] \). To simplify the presentation, we may without loss of generality assume that \( q = 1 \) by allowing \( \{c_t\} \) to be nonintegers. We next have the following result which will serve as a key to prove Theorem 5.

**Lemma 11.** Let \( S_1 \) and \( S_2 = S^-_2 \cup S^+_2 \) be two disjoint sets of items. Let \( i, j, k \) be three items not in either set such that:

1. \( d_m \leq d_j \leq d_i, \) for all items \( m \in S^-_2 \).
2. \( d_i \leq d_k \leq d_m, \) for all items \( m \in S^+_2 \).

Then, we have that

\[ \Delta \mathcal{P}(S_1 \cup \{j, k\}, S_2) \leq \Delta \mathcal{P}(S_1 \cup \{i\}, S_2). \] (17)

**Proof of Lemma 11.** We begin with two observations.

**Observation 1:** Using Lemma 8, we can determine \( \Delta \mathcal{P}(S_1 \cup \{j, k\}, S_2) \) as follows: We first fix an ordering of \( S_1 \) and assign them using Algorithm 7. This gives some residual capacity vector \( \omega'' \). The problem of finding \( \Delta \mathcal{P}(S_1 \cup \{j, k\}, S_2) \) under capacity vector \( \omega'' \) now reduces to finding \( \Delta \mathcal{P}(\{j, k\}, S_2) \) under capacity vector \( \omega'' \). Similarly, finding \( \Delta \mathcal{P}(S_1 \cup \{i\}, S_2) \) under capacity vector \( \omega \) reduces to finding \( \Delta \mathcal{P}(\{i\}, S_2) \) under capacity vector \( \omega'' \).

**Observation 2:** It suffices to prove the Lemma for \( |S_2| = 1 \).

We therefore consider two cases, based on whether the item \( m \) in \( S_2 \) has \( d_m \leq d_j \leq d_i \) or \( d_m \geq d_k \geq d_i \). Note that we have reduced to a case where we only need to worry about items \( i, j, k, m \) and capacity availability \( \omega'' \).
Case: $d_m \leq d_j \leq d_i$

To find incremental penalty:

$$\Phi^{(i,m)}_e - \Phi^{(i)}_e$$

we will first add item $i$ and then $m$ according to Algorithm 7. Similarly, for

$$\Phi^{(j,k,m)}_e - \Phi^{(j,k)}_e$$

we first add item $j$, then $k$ and then $m$. We claim that if item $m$ does not pay a penalty in the latter case (when added to $\{j, k\}$), then it does not pay a penalty when added to $\{i\}$. To see why, if $m$ does not pay a penalty when added to $\{j, k\}$, then it must be that

$$\sum_{t \leq d_j} c_t \geq 2, \quad \sum_{t \leq d_m} c_t \geq 1.$$ 

In this case, when adding item $i$, there is still residual capacity left for matching $m$.

Case: $d_i \leq d_k \leq d_m$

In this we argue that if $m$ pays a penalty when added to $i$, then it must pay a penalty when added to $\{j, k\}$. If $m$ pays penalty for $i$, then:

$$\sum_{t \leq d_i} c_t \leq 1, \quad \sum_{d_i < t \leq d_m} c_t = 0.$$ 

In this case when we first add $k$, it uses up any capacity $c_t \leq d_i$, leaving $m$ to pay a penalty.

Therefore, in either case, the incremental overflow units when adding item $m$ to item $i$ is at most the incremental overflow units when adding $m$ to $\{j, k\}$.

With the above lemmas, we are in a position to prove Theorem 5.

Proof of Theorem 5. First, suppose that without loss of generality, the items in $S_p$ are added exactly in the order of $g_1, \ldots, g_l$. Our proof is done by defining $G_i$ and $S^*_i$ inductively, and show that

$$\mathcal{P}(S^*) \leq 2\mathcal{P}(G_1) + \Delta\mathcal{P}(G_i, S^*_i), \quad \forall i \leq \min\{l, m\} \text{ s.t. } S^*_i \text{ is well-defined.}$$

Base Case. Let $G_1 = \{g_1\}$ and let $S^* = S^{*-} \cup S^{*+}$ where $S^{*-} := \{j \in S^* \mid d_j < d_1\}$ and $S^{*+} := \{j \in S^* \mid d_j \geq d_1\}$. Define

$$S^*_i = \begin{cases} S^* \setminus \{g_1\}, & \text{if } g_1 \in S^* \\ S^* \setminus \{o', o''\}, & \text{if } g_1 \notin S^* \end{cases}$$

where $o' \in S^* : d_{o'} \leq d_{g_1}, \forall i \in S^{*-}$, and $o'' \in S^* : d_{o''} \leq d_{g_1}, \forall j \in S^{*+}$, i.e., $o'$ is an item in $S^*$ with deadline no later than $g_1$ but no earlier than the deadlines of items in $S^{*-}$, and $o''$ is an item in $S^*$ with deadline no earlier than $g_1$ but no later than the deadlines of items in $S^{*+}$ (if such $o'$ or $o''$ does not exist, then simply ignore it). Then, we have the two cases:

- $g_1 \in S^*$.

$$\mathcal{P}(S^*) = \Delta\mathcal{P}(\emptyset, S^*) = \Delta\mathcal{P}(\emptyset, \{g_1\}) + \Delta\mathcal{P}(\{g_1\}, S^*_i)$$

$$\leq 2\mathcal{P}(G_1) + \Delta\mathcal{P}(G_1, S^*_i)$$
where the inequality follows directly from the fact that \( \mathcal{P}(G_1) = \Delta \mathcal{P}(\emptyset, \{g_1\}) \) is nonnegative.

- \( g_1 \notin S^* \). First note that
  \[
  \Delta \mathcal{P}(\emptyset, \{o', o''\}) = \Delta \mathcal{P}(\emptyset, \{o'\}) + \Delta \mathcal{P}(\{o'\}, \{o''\}) \\
  \leq \Delta \mathcal{P}(\emptyset, \{o'\}) + \Delta \mathcal{P}(\emptyset, \{o''\}) \\
  \leq \Delta \mathcal{P}(\emptyset, \{g_1\}) + \Delta \mathcal{P}(\emptyset, \{g_1\}) = 2 \Delta \mathcal{P}(\emptyset, \{g_1\}) = 2 \mathcal{P}(G_1),
  \]

where the first inequality follows from Lemma 10 and the second inequality follows from the greedy algorithm that \( g_1 \) gives the greatest incremental profit.

On the other hand, by Lemma 11, we also have that
\[
\Delta \mathcal{P}(\{o', o''\}, S^*_i) \leq \Delta \mathcal{P}(G_1, S^*_i).
\]
Combining the above two inequalities, we conclude that
\[
\mathcal{P}(S^*) = \Delta \mathcal{P}(\emptyset, S^*) = \Delta \mathcal{P}(\emptyset, \{o', o''\}) + \Delta \mathcal{P}(\{o', o''\}, S^*_i) \\
\leq 2 \mathcal{P}(G_1) + \Delta \mathcal{P}(G_1, S^*_i)
\]

**Induction Step.** Assume that \( \mathcal{P}(S^*) \leq 2 \mathcal{P}(G_i) + \Delta \mathcal{P}(G_i, S^*_i) \), we define \( G_{i+1} = G_i \cup \{g_{i+1}\} \) and let \( S^*_i = S^{*-}_{i-1} \cup S^*_i \) where \( S^{*-}_i := \{ j \in S^*_i \mid d_j < d_{g_i} \} \) and \( S^*_i := \{ j \in S^*_i \mid d_j \geq d_{g_i} \} \). Define
\[
S^*_i+1 = \begin{cases} 
  S^*_i \setminus \{g_{i+1}\}, & \text{if } g_{i+1} \in S^*_i \\
  S^*_i \setminus \{o', o''\}, & \text{if } g_{i+1} \notin S^*_i 
\end{cases}
\]
where where \( o' \in S^*_i : d_{o'} \leq d_{g_i}, \forall i' \in S^{*-}_i \), and \( o'' \in S^*_i : d_{g_i} \leq d_{o''} \leq d_{j'}, \forall i' \in S^*_i \), i.e., \( o' \) is an item in \( S^*_i \) with deadline no later than \( g_i \) but no earlier than the deadlines of items in \( S^{*-}_i \), and \( o'' \) is an item in \( S^*_i \) with deadline no earlier than \( g_i \) but no later than the deadlines of items in \( S^*_i \) (if such \( o' \) or \( o'' \) does not exist, then simply ignore it). Then, we have in the two cases:

- \( g_{i+1} \in S^*_i \).
  \[
  \mathcal{P}(S^*) \leq 2 \mathcal{P}(G_i) + \Delta \mathcal{P}(G_i, S^*_i) = 2 \mathcal{P}(G_i) + \Delta \mathcal{P}(G_i, \{g_{i+1}\}) + \Delta \mathcal{P}(G_{i+1}, S^*_{i+1}) \\
  \leq 2 \mathcal{P}(G_i) + 2 \Delta \mathcal{P}(G_i, \{g_{i+1}\}) + \Delta \mathcal{P}(G_{i+1}, S^*_{i+1}) = 2 \mathcal{P}(G_{i+1}) + \Delta \mathcal{P}(G_{i+1}, S^*_{i+1})
  \]
  where the first inequality follows from the induction assumption and the second inequality follows directly from the fact that \( \Delta \mathcal{P}(G_i, \{g_{i+1}\}) \) is nonnegative.

- \( g_{i+1} \notin S^*_i \). First note that
  \[
  \Delta \mathcal{P}(G_i, \{o', o''\}) = \Delta \mathcal{P}(G_i, \{o'\}) + \Delta \mathcal{P}(G_i \cup \{o'\}, \{o''\}) \\
  \leq \Delta \mathcal{P}(G_i, \{o'\}) + \Delta \mathcal{P}(G_i, \{o''\}) \\
  \leq \Delta \mathcal{P}(G_i, \{g_{i+1}\}) + \Delta \mathcal{P}(G_i, \{g_{i+1}\}) = 2 \Delta \mathcal{P}(G_i, \{g_{i+1}\}),
  \]
  where the first inequality follows from Lemma 10 and the second inequality follows from the greedy algorithm that \( g_{i+1} \) adds the greatest incremental profit to \( G_i \).
On the other hand, by Lemma 11, we also have that
\[
\Delta P \left( G_i \cup \{o', o''\}, S^*_{i+1} \right) \leq \Delta P \left( G_{i+1}, S^*_{i+1} \right).
\]

Combining the above two inequalities, we conclude that
\[
\mathcal{P}(S^*) \leq 2\mathcal{P}(G_i) + \Delta \mathcal{P}(G_i, S^*_i) = 2\mathcal{P}(G_i) + \Delta \mathcal{P}(G_i, \{o', o''\}) + \Delta P \left( G_i \cup \{o', o''\}, S^*_{i+1} \right)
\]
\[
\leq 2\mathcal{P}(G_i) + 2\Delta P \left( G_i, \{g_{i+1}\} \right) + \Delta P \left( G_{i+1}, S^*_i \right)
\]
\[
\leq 2\mathcal{P}(G_{i+1}) + \Delta P \left( G_{i+1}, S^*_i \right)
\]
This completes the induction step. Note that at each step, \( S^*_{i+1} \subsetneq S^*_i \) and \( G_i \subsetneq G_{i+1} \). In the end, we will reach some \( i' \) such that \( S^*_{i'} = \emptyset \) or \( G_{i'} = S_p \) and \( S^*_{i'} \neq \emptyset \). In the first case, we have that
\[
\mathcal{P}(S^*) \leq 2\mathcal{P}(G_{i'}) + \Delta \mathcal{P}(G_{i'}, S^*_{i'}) = 2\mathcal{P}(G_{i'}) + 0 \leq 2\mathcal{P}(S_p).
\]
In the second case, i.e., \( G_{i'} = S_p \) and \( S^*_{i'} \neq \emptyset \), we again have that \( \mathcal{P}(S^*) \leq 2\mathcal{P}(G_{i'}) + \Delta \mathcal{P}(G_{i'}, S^*_{i'}) \). Now if \( \Delta \mathcal{P}(G_{i'}, S^*_{i'}) > 0 \), then we can add the items in \( S^*_{i'} \) to \( S_p \) and still increase the profit, which violates the greedy algorithm. Thus, it must be that \( \Delta \mathcal{P}(G_{i'}, S^*_{i'}) \leq 0 \). Then we would have
\[
\mathcal{P}(S^*) \leq 2\mathcal{P}(G_{i'}) + \Delta \mathcal{P}(G_{i'}, S^*_{i'}) \leq 2\mathcal{P}(S_p).
\]
In conclusion, we have that \( \mathcal{P}(S^*) \leq 2\mathcal{P}(S_p) \), or equivalently \( \mathcal{P}(S_p) \geq \frac{1}{2} \mathcal{P}(S^*) \). This completes the proof of Theorem 5. ■

B Alternative FPTAS for MPBKP

In this section, we introduce another FPTAS for MPBKP, which has time complexity \( \tilde{O} \left( n + \frac{T^2}{r^2} \right) \). To roughly describe the main idea, we will again adopt the functional approach to approximate (6). Instead of having an approximation of \( f_{I(t)} \) for each \( t \) directly from Lemma 1, we further partition \( I(t) \) into \( m + 1 \) subsets (\( m \) being specified later), i.e., \( I(t) := I(t)_0 \sqcup I(t)_1 \sqcup \cdots \sqcup I(t)_m \), where items in each subset have approximately the same reward. Then, we have that \( f_{I(t)} = f_{I(t)_0} \oplus f_{I(t)_1} \oplus \cdots \oplus f_{I(t)_m} := \oplus^m_{j=0} f_{I(t)_j} \), and by noting that the \((\max, +)\)-convolution \( \oplus \) is commutative, the function \( f_t \) as defined in (6) can be computed as
\[
f_t := \begin{cases} f_{I(t)_1}^c, & t = 1, \\ (f_{t-1} \oplus f_{I(t)})^c, & t \geq 2, \end{cases}
\]
and (18) can be computed more efficiently due to some special properties of \( f_{I(t)_j} \).

Before proceeding to the actual algorithm, we first have some preliminaries. A monotone step function \( f_{I}(c) \) with steps at \( c_1, c_2, \ldots, c_l \) is called \textit{r-uniform} if it satisfies both of the following conditions:

1. \( \forall c \in \mathbb{R}^+, f_{I}(c) = kr \) for some nonnegative integer \( k \),
2. \( \exists c_j \) s.t. \( f_{I}(c_j) = kr \Rightarrow \exists c_{j'} \) s.t. \( f_{I}(c_{j'}) = k'r, \forall k' \leq k \) nonnegative integers.

The monotone step function \( f_{I}(c) \) with steps at \( c_1, c_2, \ldots, c_l \) is called \textit{pseudo-concave} if \( c_{j+2} - c_{j+1} \geq c_{j+1} - c_j, \forall j = 1, \ldots, l - 2 \). The \textit{range} of a function \( f \) is the set of all possible function values. We then introduce the
following lemma from Chan (2018) for approximating $f \oplus g$ when $g$ is $r$-uniform and pseudo-concave.

Lemma 12 (Chan (2018)). Let $f$ and $g$ be monotone step functions with total complexity $l$ and ranges contained in $\{-\infty, 0\} \cup \{A, B\}$. Then we can compute a monotone step function that approximates $f \oplus g$ with factor $1 + \mathcal{O}(e')$ and complexity $\mathcal{O}\left(\frac{1}{r}\right)$ in $\mathcal{O}(l) + \mathcal{O}\left(\frac{1}{r}\right)$ time if $g$ is $r$-uniform and pseudo-concave.

With the above lemma, we present Algorithm 8 for MPBKP.

Algorithm 8 FPTAS for MPBKP in $\mathcal{O}\left(n + T^2 / \epsilon^3\right)$

| Input: $[n], c_1, \ldots, c_T$ | $\triangleright$ Set of items to be packed, cumulative capacities up to each time $t$ |
| Output: $\hat{f}_t$ | $\triangleright$ Approximation of function $f_t$ |
| 1: Discard all items with $r_i \leq \frac{1}{n} \max_j r_j$ and relabel the items | $\triangleright$ Lower bound of solution value |
| 2: $r_0 \leftarrow \min_i r_i$ | $\triangleright$ Round down the reward of each item |

In Algorithm 8, we first discard all items with reward $r_i \leq \frac{1}{n} \max_j r_j$. The maximum we could lose is $n \cdot \frac{1}{n} \max_j r_j = \epsilon \max_j r_j$, which is at most $\epsilon$ fraction of the optimal value. We next round down the rewards of all remaining items to the nearest $r_0 \cdot (1 + \epsilon)^k$, where $r_0 := \min_j r_j$ and $k$ is some nonnegative integer, so we lose at most a fraction of $(1 + \epsilon)$ in the rounding, and the number of distinct rounded rewards is bounded by $m = \left\lceil \log_{1+\epsilon}\left(\frac{c_i}{r_0}\right) \right\rceil = \tilde{\mathcal{O}}\left(\frac{1}{r}\right)$. We begin with initializing $\hat{f}_0 = -\infty$. Then, for period $t = 1$, we partition $\mathcal{I}(1) = \bigcup_{j=0}^m \mathcal{I}(1)_j$ where all items in $\mathcal{I}(1)_j$ have rounded reward $r_0 \cdot (1 + \epsilon)^j$. Denote by $\hat{\mathcal{I}}(1)_j$ these items with rounded rewards, and by adding these items greedily in nonincreasing order of their sizes, we obtain $\hat{f}_{\mathcal{I}(1)_j}$, which is a $(1 + \epsilon)$ approximation of $f_{\mathcal{I}(1)_j}$, and is $r_0 \cdot (1 + \epsilon)^j$-uniform and pseudo-concave. By applying Lemma 12 for $m + 1$ times (with $e'$ to be specified later), we obtain $\hat{f}_0 \oplus \hat{f}_{\mathcal{I}(1)_0} \oplus \hat{f}_{\mathcal{I}(1)_1} \oplus \cdots \oplus \hat{f}_{\mathcal{I}(1)_m} = \hat{f}_0 \oplus \hat{f}_{\mathcal{I}(1)}$, which approximates $f_0 \oplus f_{\mathcal{I}(1)}$ with an accumulative approximation factor $(1 + \epsilon)(1 + \epsilon')^{m+1}$, and is computed in total time $\mathcal{O}(n_1) + \tilde{\mathcal{O}}\left(\frac{m}{r_0}\right)$. Then, to ensure feasibility, $\hat{f}_1$ is obtained by taking truncation $c_1$ on $\hat{f}_0 \oplus \hat{f}_{\mathcal{I}(1)}$, which becomes a $(1 + \epsilon)(1 + \epsilon')^{m+1}$ approximation of $f_1$. We then move to period 2 and continue this pattern of partition, convolutions, and truncation. In the end as we reach period $T$, $\hat{f}_T$ would only contain feasible solutions to (1), and approximates $f_T$ with accumulated approximation factor $(1 + \epsilon)(1 + \epsilon')^{(m+1)T} \approx (1 + \epsilon)(1 + (m + 1)T\epsilon)$. Formally, we have the following lemma which shows the approximation factor of $\hat{f}_t$ to $f_t$.

Lemma 13. Let $\hat{f}_t$ be the functions obtained from Algorithm 8, and let $f_t$ be defined as in (6). Then, $\hat{f}_t$ approximates $f_t$ with factor $(1 + \epsilon)(1 + \epsilon')^{(m+1)T}$, i.e., $\hat{f}_t(c) \leq f_t(c) \leq (1 + \epsilon)(1 + \epsilon'(m+1)T)\hat{f}_t(c)$ for all $0 \leq c \leq c_t$.

The proof of Lemma 13 relies on the following fact.
**Lemma 14.** At any period $t$, after running the inner “for” loop of Algorithm 8, we have that $(1 + \epsilon')^{m+1} \tilde{f}_t \geq \tilde{f}_{t-1} \oplus \hat{f}_{\mathcal{I}(t)_0} \oplus \hat{f}_{\mathcal{I}(t)_1} \oplus \cdots \oplus \hat{f}_{\mathcal{I}(t)_m}$.

**Proof of Lemma 14.** We prove by induction on $j = 0, 1, \ldots, m$. Base case is when $j = 0$, i.e., after the first round of the inner “for” loop, by Lemma 12, we have that $(1 + \epsilon') \tilde{f}_t \geq \tilde{f}_{t-1} \oplus \hat{f}_{\mathcal{I}(t)_0}$. For the induction step, assume that after $j$ rounds of the inner “for” loop, $(1 + \epsilon')^j \tilde{f}_t \geq \tilde{f}_{t-1} \oplus \hat{f}_{\mathcal{I}(t)_0} \oplus \cdots \oplus \hat{f}_{\mathcal{I}(t)_{j-1}}$. We show that after $j + 1$ rounds, $(1 + \epsilon')^{j+1} \tilde{f}_t \geq \tilde{f}_{t-1} \oplus \hat{f}_{\mathcal{I}(t)_0} \oplus \cdots \oplus \hat{f}_{\mathcal{I}(t)_{j}}$. As a notation, we denote by $\tilde{f}_t^{\text{old}}$ the $\tilde{f}_t$ right before the $(j + 1)$th round of the inner “for” loop, and by $\tilde{f}_t^{\text{new}}$ the $\tilde{f}_t$ right after the $(j + 1)$th round of the inner “for” loop. Then, from Lemma 12 we have that $(1 + \epsilon') \tilde{f}_t^{\text{new}} \geq \tilde{f}_t^{\text{old}} \oplus \hat{f}_{\mathcal{I}(t)_j}$, which implies that

$$(1 + \epsilon')^{j+1} \tilde{f}_t^{\text{new}} \geq (1 + \epsilon')^j \tilde{f}_t^{\text{old}} \oplus \hat{f}_{\mathcal{I}(t)_j} \geq \tilde{f}_{t-1} \oplus \hat{f}_{\mathcal{I}(t)_0} \oplus \cdots \oplus \hat{f}_{\mathcal{I}(t)_{j}} \oplus \hat{f}_{\mathcal{I}(t)_j},$$

where the second inequality follows from the induction assumption. This finishes the induction step, and thus the proof of the lemma.

With Lemma 14 at hand, we now prove Lemma 13.

**Proof of Lemma 13.** By the construction of $\tilde{f}_t$, it should be clear that $\tilde{f}_t \leq f_t$. We prove that $(1 + \epsilon)(1 + \epsilon')^{m+1} \tilde{f}_t \geq f_t$ by induction on $t$. Base case is when $t = 1$, we have that $(1 + \epsilon)(1 + \epsilon')^{m+1} \tilde{f}_1 = (1 + \epsilon)(1 + \epsilon')^{m+1} f_1 = f_1$, which implies that $\tilde{f}_1 \geq f_1$.

After partitioning $\mathcal{I}(t) = \mathcal{I}(t)_0 \cup \mathcal{I}(t)_1 \cup \cdots \cup \mathcal{I}(t)_m$, for any $i \in \mathcal{I}(t + 1)$, by the rounding down, we have that $(1 + \epsilon) \tilde{f}_i \geq r_i \geq f_i$, which further implies that $(1 + \epsilon) \tilde{f}_{\mathcal{I}(t+1)_j} \geq \tilde{f}_{\mathcal{I}(t+1)_j} \geq f_{\mathcal{I}(t+1)_j}, \forall j = 0, 1, \ldots, m$. Thus,

$$(1 + \epsilon) \left( \tilde{f}_{\mathcal{I}(t+1)_0} \oplus \tilde{f}_{\mathcal{I}(t+1)_1} \oplus \cdots \oplus \tilde{f}_{\mathcal{I}(t+1)_m} \right) \geq f_{\mathcal{I}(t+1)} \geq \tilde{f}_{\mathcal{I}(t+1)_0} \oplus \tilde{f}_{\mathcal{I}(t+1)_1} \oplus \cdots \oplus \tilde{f}_{\mathcal{I}(t+1)_m},$$

which, together with the induction assumption, implies that

$$(1 + \epsilon)(1 + \epsilon')^{m+1} \left( \tilde{f}_t \oplus \tilde{f}_{\mathcal{I}(t+1)_0} \oplus \tilde{f}_{\mathcal{I}(t+1)_1} \oplus \cdots \oplus \tilde{f}_{\mathcal{I}(t+1)_m} \right) \geq f_t \oplus f_{\mathcal{I}(t+1)}.$$

By Lemma 14, after the inner “for” loop in Algorithm 8, we have that $(1 + \epsilon')^{m+1} \tilde{f}_{t+1} \geq \tilde{f}_t \oplus \hat{f}_{\mathcal{I}(t+1)_0} \oplus \hat{f}_{\mathcal{I}(t+1)_1} \oplus \cdots \oplus \hat{f}_{\mathcal{I}(t+1)_m}$, which implies that

$$(1 + \epsilon)(1 + \epsilon')^{m+1} \tilde{f}_{t+1} \geq (1 + \epsilon)(1 + \epsilon')^{(m+1)(t+1)} \left( \tilde{f}_t \oplus \hat{f}_{\mathcal{I}(t+1)_0} \oplus \hat{f}_{\mathcal{I}(t+1)_1} \oplus \cdots \oplus \hat{f}_{\mathcal{I}(t+1)_m} \right) \geq f_t \oplus f_{\mathcal{I}(t+1)}.$$

Taking truncation on both sides, we conclude that

$$(1 + \epsilon)(1 + \epsilon')^{(m+1)(t+1)} \tilde{f}_{t+1} = (1 + \epsilon)(1 + \epsilon')^{(m+1)(t+1)} \tilde{f}_{t+1}^{\text{ct+1}} \geq (f_t \oplus f_{\mathcal{I}(t+1)})^{\text{ct+1}} = f_{t+1}.$$

This finishes the induction step, and thus the proof of the lemma.
Lemma 13 and Proposition 1 together imply that $\tilde{f}_T(c_T)$, obtained from Algorithm 8, approximates the optimal value of MPBKP (1) by a factor of $(1 + \epsilon)(1 + \epsilon'\frac{(m+1)T}{m})$. In Algorithm 8, during each of the periods $t = 1, \ldots, T$, approximately computing the $(\max, +)$-convolutions on $\tilde{f}_T \oplus \tilde{f}_{T(t)}$ for all $j = 0, 1, \ldots, m$ take total time $\tilde{O}(n_t + (m + 1)/\epsilon')$. Therefore, Algorithm 8 has total runtime $\tilde{O}(n + (m + 1)T/\epsilon')$. As a result, we have the following proposition.

**Proposition 4.** Taking $\epsilon = mT\epsilon'$ and $m = \tilde{O}(1/\epsilon)$, Algorithm 8 achieves $(1 + \epsilon)$-approximation for MPBKP in $\tilde{O}\left(n + \frac{m}{\epsilon^2}\right)$.

### C Alternative FPTAS for MPBKP-S

In this section, we provide an FPTAS for the MPBKP-S with time complexity $\mathcal{O}\left(\frac{n^2 \log n}{\epsilon}\right)$. Following the classical approach for “0-1” knapsack problems (see, e.g., Vazirani (2013)), we round down the reward of each item so that the optimal solution for the MPBKP under the new rounded rewards is upper bounded by some polynomial of $n$ and $1/\epsilon$, and thus the naive pseudo-polynomial dynamic program becomes a polynomial time algorithm.

We assume that the items are initially sorted and relabeled in the increasing order of their deadlines, i.e., $d_1 \leq d_2 \leq \cdots \leq d_n$. Further, assume that we have a guess $P_0$ that satisfies (10). Then, we choose a discretization quantum $\kappa := \epsilon P_0 / 2n$ and define rounded rewards $\tilde{r}_i := \left\lfloor \frac{r_i}{\kappa} \right\rfloor$. We then have $\mathcal{P}(S^*) \leq \frac{4n}{\kappa} \epsilon \kappa$.

For a solution $S = \{S(1) \cup S(2) \cup \cdots \cup S(T)\}$ where $S(t)$ is the set of items with deadline $t$. Let the items in $S(t)$ be indexed as $S(t) = (i_1^{(t)}, \ldots, i_{S(t)}^{(t)})$ in the order in which Algorithm 9 considers them, we define the rounded profit of $S$ as:

$$\hat{\mathcal{P}}(S) = \hat{\mathcal{R}}(S) - \sum_{t=1}^{T} \sum_{k=1}^{S(t)} \left[ B \left( \sum_{\ell \leq k} q_{i_{\ell}^{(t)}} \right) - \max_{0 \leq t' < t} \left\{ c_{t} - c_{t'} - \sum_{t'+1 \leq \tau \leq t} Q(S(\tau)) \right\} \right]^{+} \right]_{\kappa}. \tag{19}$$

Let us also define a single period change in rounded profit for a set of items $S = (i_1, \ldots, i_S)$ with knapsack capacity $c$ as:

$$\Delta \hat{\mathcal{P}}(S, c) = \hat{\mathcal{R}}(S) - \sum_{k=1}^{S} \left[ B \left( \sum_{\ell \leq k} q_{i_{\ell}} - c \right) \right]^{+} \right]_{\kappa}. \tag{20}$$

Let $\hat{A}(i, p)$ be the maximum capacity left at time $d_i$ when earning rounded profit at least $p$ using items $\{1, \ldots, i\}$ with rounded down rewards $\tilde{r}$, equivalently,

$$\hat{A}(i, p) := \max_{\{S \subseteq \{1, \ldots, i\} \mid \mathcal{P}(S) \geq p\}} \max_{0 \leq t' < d_i} \left\{ c_{d_i} - c_{t'} - \sum_{t'+1 \leq \tau \leq d_i-1} Q(S(\tau)) \right\}. \tag{21}$$

If it is not possible to earn profit $p$ at time $d_i$ using items $\{1, \ldots, i\}$ with rounded down rewards, i.e., no $S \subseteq \{1, \ldots, i\}$ exists such that $\hat{\mathcal{P}}(S) \geq p$, then $\hat{A}(i, p)$ is labeled $-\infty$. The DP table runs for $i = 1, \ldots, n$ and $p = 0, \kappa, \ldots, \left\lceil \frac{4n}{\epsilon} \right\rceil \kappa$. We then have Algorithm 9, which returns an exact optimal solution of $\hat{\mathcal{P}}(S)$ under the
rounded rewards and rounded penalties.

Algorithm 9 DP with rounded down rewards for MPBKP-S

1: Define \( \kappa = \frac{c_k}{c_{\max}} \)
2: Define \( \hat{\kappa} = \kappa \left\lceil \frac{\kappa}{\kappa} \right\rceil \)

// \( A(i, p) \) = max capacity left at time \( d_i \) when earning (rounded) profit at least \( p \) by selecting items in \( \{1, \ldots, i\} \) with rounded down rewards \( \hat{p} \)
3: Initialize \( \hat{A}(0, p) = \begin{cases} 0 & p = 0, \\ -\infty & p > 0. \end{cases} \)

4: for \( t = 1, \ldots, T \) do
5: \( i = I(t - 1) + 1 \)
6: for \( p = \left\{ 0, 1, \ldots, \left\lfloor \frac{4n}{\epsilon} \right\rfloor \right\} \cdot \kappa \) do
7: \( \hat{A}(i, p) := \hat{A}(i - 1, p) + c_t - c_{t - 1} \)
8: end for
9: for \( \hat{p} = \left\{ \left\lfloor \frac{4n}{\epsilon} \right\rfloor, \left\lceil \frac{4n}{\epsilon} \right\rceil - 1, \ldots, 1 \right\} \cdot \kappa \) do
10: \( p = \hat{p} + \hat{r}_i - \left[ B(q_i - \max\{0, \hat{A}(i - 1, \hat{p}) + (c_t - c_{t - 1})\}) + \right] \)
11: \( \hat{A}(i, p) = \max\{\hat{A}(i, p), \hat{A}(i - 1, \hat{p}) + (c_t - c_{t - 1}) - q_i\} \)
12: end for
13: for \( p = \left\{ \left\lfloor \frac{4n}{\epsilon} \right\rfloor, \left\lceil \frac{4n}{\epsilon} \right\rceil - 1, \ldots, 1 \right\} \cdot \kappa \) do
14: if \( \hat{A}(i, p - \kappa) < \hat{A}(i, p) \) then
15: \( \hat{A}(i, p - \kappa) = \hat{A}(i, p) \)
16: end if
17: end for
18: for \( i = I(t - 1) + 2, \ldots, I(t) \) do
19: for \( p = \left\{ 0, 1, \ldots, \left\lfloor \frac{4n}{\epsilon} \right\rfloor \right\} \cdot \kappa \) do
20: \( \hat{A}(i, p) := \hat{A}(i - 1, p) \)
21: end for
22: for \( \hat{p} = \left\{ \left\lfloor \frac{4n}{\epsilon} \right\rfloor, \left\lceil \frac{4n}{\epsilon} \right\rceil - 1, \ldots, 1 \right\} \cdot \kappa \) do
23: \( p = \hat{p} + \hat{r}_i - \left[ B(q_i - \max\{0, \hat{A}(i - 1, \hat{p})\}) + \right] \)
24: \( \hat{A}(i, p) = \max\{\hat{A}(i, p), \hat{A}(i - 1, \hat{p}) - q_i\} \)
25: end for
26: for \( p = \left\{ \left\lfloor \frac{4n}{\epsilon} \right\rfloor, \left\lceil \frac{4n}{\epsilon} \right\rceil - 1, \ldots, 1 \right\} \cdot \kappa \) do
27: if \( \hat{A}(i, p - \kappa) < \hat{A}(i, p) \) then
28: \( \hat{A}(i, p - \kappa) = \hat{A}(i, p) \)
29: end if
30: end for
31: end for
32: end for

Proof of Correctness of Algorithm 9. We show that \( \hat{A}(i, p) \) returned by the algorithm satisfies (21) by induction on \( i \). The base case \( (i = 0) \) is vacuously true. Now we assume that (21) holds for all \( p \in \{0, 1, \ldots, \left\lfloor 4n/\epsilon \right\rceil \cdot \kappa \) and for all \( k \in [i - 1] \). Consider some \( p \in \{0, 1, \ldots, \left\lfloor 4n/\epsilon \right\rceil \cdot \kappa \), and let \( S^* \) be any set achieving the maximum in (21) so that \( \mathcal{P}(S) \geq p \). We will show that \( \hat{A}(i, p) \) is at least the leftover capacity under solution \( S^* \) via case analysis:

- Case \( i \notin S^* \): In this case, the leftover capacity under \( S^* \) is the leftover capacity by \( d_i \), which is the sum of leftover capacity in \( S^* \) by \( d_{i-1} \) and \( c_{d_i} - c_{d_{i-1}} \). By induction hypothesis, \( \hat{A}(i - 1, p) \) is no less than the leftover capacity of \( S^* \) by \( d_{i-1} \), and therefore, by lines (7,11) and (20,24), \( \hat{A}(i, p) \geq \hat{A}(i - 1, p) + c_{d_i} - c_{d_{i-1}} \)
which in turn is no less than the leftover capacity under \( S^* \) by \( d_i \). By optimality of \( S^* \), all the inequalities must be equalities.

- **Case \( i \in S^* \):** Let \( S' = S^* \setminus \{i\} \), and let \( p' = \hat{P}(S') \) be its rounded profit. Then by induction hypothesis, \( \hat{A}(i - 1, p') \) is no less than the leftover capacity under \( S' \) by \( d_{i-1} \). Further, by packing item \( i \) in the solution corresponding to \( A(i - 1, p') \), the change in profit is larger than by packing item \( i \) in \( S' \) (the penalty is no less under \( S' \) since it has weakly smaller leftover capacity). Therefore, packing item \( i \) in the solution corresponding to \( \hat{A}(i - 1, p') \) gives a solution with at least as large a rounded profit as \( p \) and at least as much leftover capacity by \( d_i \) as \( S^* \). Therefore, in turn \( \hat{A}(i, p) \) is at least as much as the leftover capacity in \( S^* \). Since we assume \( S^* \) to have the largest leftover capacity with profit at least \( p \), all the inequalities must be equalities.

Our next result gives the approximation guarantee for Algorithm 9.

**Lemma 15.** Let \( S^* \) be the optimal solution set to the original MPBKP-S, and \( P_0 \) satisfy (10). Let \( S' \) denote the optimal solution set by Algorithm 9, i.e., \( S' \) is the solution set corresponding to \( \hat{A}(n, p^*) \) where \( p^* \) is the maximum \( p \) such that \( \hat{A}(n, p) > -\infty \). Then,

\[
\mathcal{P}(S') \geq p^* \geq (1 - \epsilon)\mathcal{P}(S^*).
\]

**Proof of Lemma 15.** For any item \( i \), because of rounding down, \( \hat{r}_i \) is smaller than \( r_i \). Also there are at most \( n \) rounding ups on the penalties in \( S^* \), each by not more than \( \kappa \). Then,

\[
\mathcal{P}(S^*) - \hat{P}(S^*) \leq 2n\kappa.
\]

The dynamic programming step must return a set, \( S' \), at least as good as \( S^* \) under the new profit. Therefore,

\[
\mathcal{P}(S') \geq \hat{P}(S') = p^* \geq \hat{P}(S^*) \geq \mathcal{P}(S^*) - 2n\kappa = \mathcal{P}(S^*) - \epsilon P_0 \geq (1 - \epsilon)\mathcal{P}(S^*),
\]

where first inequality follows because the rewards are rounded down and the penalties are rounded up in calculation of \( \hat{P} \), second inequality follows because \( S' \) is the optimal set for objective \( \hat{P} \), the third inequality follows because \( |S^*| \leq n \) and \( T \leq n \), and the last inequality follows from (10) that \( \mathcal{P}(S^*) \geq P_0 \).

It remains to find \( P_0 \) which satisfies (10). Since \( \mathcal{P}(S^*) \leq \hat{P} \), we can enumerate \( P_0 \) from \( \hat{P}/2, \hat{P}/4, \hat{P}/8, \ldots \), and one of them must satisfy (10). The FPTAS is presented as Algorithm 10.

**Algorithm 10** FPTAS for MPBKP-S in \( O(n^2\log n/\epsilon) \)

```
1: \( P_0 \leftarrow \hat{P} \)
2: \( p^* \leftarrow 0 \)
3: while \( p^* < (1 - \epsilon)P_0 \) do
4: \( P_0 \leftarrow \frac{P_0}{2} \)
5: Run Algorithm 9 with the current \( P_0 \).
6: \( p^* \leftarrow \max_{P} \left\{ P \in \left\{ P \in \mathbb{R} \mid A(n, p) \geq -\infty \right\} : P \right\} \)
7: end while
```
**Theorem 6.** Algorithm 10 is a fully polynomial approximation scheme for the MPBKP-S, which achieves \((1 - \epsilon)\) factor of optimal with running time \(O\left(\frac{n^2 \log n}{\epsilon}\right)\).

**Proof of Theorem 6.** Time complexity: When \(P_0\) satisfies (10), by Lemma 15 we have that
\[
p^* \geq (1 - \epsilon)P(S^*) \geq (1 - \epsilon)P_0.
\]
Thus, the “while” loop terminates when \(P_0\) satisfies (10), if not before \(P_0\) satisfies (10). When \(P_0\) satisfies (10), we would also have \(P(S^*)/2 \leq P_0 \leq P(S^*)\). Therefore, the number of iterations is upper bounded by
\[
\text{number of iterations} \leq \log \frac{\bar{P}/2}{P(S^*)/2} \leq \log n,
\]
where we have used the fact that \(\bar{P} \leq nP \leq nP(S^*)\). Since each iteration takes time \(O\left(n \cdot \left\lceil \frac{4n}{\epsilon}\right\rceil\right)\) we get a total time complexity of \(O\left(\frac{n^2 \log n}{\epsilon}\right)\).

**Approximation ratio:** When Algorithm 10 terminates, it returns the last \(p^*\) and the solution set \(S'\) corresponding to \(\hat{A}(n, p^*)\). If the “while” loop terminates when \(P_0 > P(S^*)\), i.e., it stops before \(P_0\) falls below \(P(S^*)\), then we have that
\[
P(S') \geq p^* \geq (1 - \epsilon)P_0 > (1 - \epsilon)P(S^*).
\]
Otherwise, from the time complexity analysis, we know that the “while” loop must terminate when \(P_0\) first falls below \(P(S^*)\), which implies that the last \(P_0\) satisfies (10). Then by Lemma 15 we again have that
\[
P(S') \geq (1 - \epsilon)P(S^*).
\]
In either case, the solution we obtained from Algorithm 10 achieves \((1 - \epsilon)\) optimal, \((1 - \epsilon)\) factor of \(P(S^*)\). ■
