Recurrence is a major issue in the treatment of diverticular disease. It is estimated that between 20% and 35% of patients who experience an acute episode of diverticulitis will go on to have a recurrence.

Recurrence can be caused by a number of factors, including surgical trauma, inflammatory changes in the bowel, and bacterial infection. It is important to identify patients who are at high risk of recurrence and to tailor their treatment accordingly.

Surgical treatment is the mainstay of management for recurrent diverticulitis, but the decision to operate should be carefully considered. Factors that should be taken into account include the number of previous episodes, the severity of symptoms, and the patient's overall health.

Conclusion

Treatment now has to be patient-tailored with special attention to the subgroup of high-risk patients. These patients must be adequately selected, identifying the impact of the disease on the quality of life and weighing in the risks of the surgical intervention.
patient who has never undergone surgical intervention for acute diverticulitis. Hupfeld et al. [14] showed that diverticular abscess formation and younger people were at a higher risk of recurrence. Similarly, Anaya and Flum [2] noted younger patients (< 50 years) had a higher rate of not only recurrence (27 vs. 17%), but also emergency colectomy/colostomy (7.5 vs. 5%). However, Katz et al. [15] disputed the assertion of increased severity of diverticulitis in young patients and found in a metaanalysis of nearly 5,000 patients aged 40–50 years that diverticular disease in this age group was not more severe than that in the elderly. Nonetheless, it was found that the frequency of representation was higher in the young and male population (RR 1.70, 95% CI 1.31–2.21) [15].

Recurrent admissions were highest in the first year of diagnosis. The risk of recurrence appeared to increase after each recurrence. However, a left colon with more than 5 cm of inflammation, presence of multiple and pan-colonic diverticula, and immunosuppression carried a medium risk only. Poletti et al. [1] followed up patients for 18 months and found that 32% of patients presented with recurrent diverticulitis. Computed tomography (CT) scan signs of evidence of gas pocket and abscess were predictors of recurrence. Age and sex were not significantly associated with the risk of recurrence. Hall et al. [7] in a study of 672 patients showed that family history of diverticulitis, long segment of colon involvement, and the presence of retroperitoneal abscess were predictors of failure of nonoperative management. However, this study also clarified that in 5 years of follow up 3.9% presented with complicated diverticulitis including fistulae, abscess, or frank perforation. Similarly, Eglington et al. [5] noted a 5% rate of complicated presentations after conservative management in a study of more than 300 patients followed up for a median period of 101 months. Interestingly, right-sided colonic diverticulitis was not associated with recurrence (HR 0.27, 95% CI 0.09–0.86). Prophylactic use of mesalamine has been explored and may reduce the frequency of recurrences [14].

Historically, surgery was advised after two attacks of uncomplicated diverticulitis and after one attack in patients younger than 40 years [16]. This has been recently challenged by a new approach to individualize treatment depending on patient immunity status, development of chronic pain, frequency of attacks, and complications the patients develop, and after some new studies that reflected on the rates of events of patients with history of acute diverticulitis. For this reason, we thought of embarking on this review to identify relevant data in support of indication, timing, and method of surgery.

### Pathophysiology

Diverticulosis is defined as the occurrence of small out-pouchings or protrusions in intestinal walls. These pockets, called diverticula, generally remain asymptomatic. However, they can become symptomatic and when they do, the condition is defined as diverticular disease which comprises a number of disorders including bleeding, diverticulitis, or segmental colitis. Diverticulitis occurs when the diverticula become inflamed. Diverticular disease presents a major economic burden in Western societies.

Typical diverticula are false or pseudo-diverticula that are composed of mucosa and submucosa herniating through the muscularis layer and covered only by serosa. This commonly occurs at the relatively weak points where the vasa recta penetrate the muscularis layer to perfuse the submucosa and mucosa.

Numerous risk factors have been associated with diverticular disease and many were studied (Table 1). In a prospective cohort that assessed the risk of diverticulitis in over 51,000 men aged 40–75 years, low dietary fiber, high intake of red meat, being overweight or obese, sedentary lifestyle, and smoking (≥ 40 pack-years) were independently associated with an increased risk of diverticulitis [17]. In contrast to previous perception, seeds, nuts, and popcorn are not associated with increased risk of diverticulitis or diverticular disease, nor were caffeine and alcohol [18]. Smoking on the other hand is not only associated with diverticular disease but also appears to confer an increased risk of perforation and abscess formation [19]. Drugs also play a significant role in the pathogenesis of diverticular disease. While nonsteroidal anti-inflam-
matory drugs, steroids, and opiates are associated with increased risk of diverticulitis and bleeding, vitamin D and statins bestow a protective effect [19–21].

Diverticulitis

With advanced inflammation, microscopic or macroscopic perforation of a diverticulum can happen due to focal necrosis and this divides diverticulitis into two categories: uncomplicated and complicated.

Uncomplicated diverticulitis is a localized inflammation of the diverticulum, while complicated diverticulitis is advanced inflammation concomitant with bleeding or the formation of a phlegmon, abscess, or fistula or associated with obstruction or purulent or fecal peritonitis. Diverticulitis happens in approximately 4% of patients with diverticulosis [22].

Because the sigmoid colon is most frequently affected, diverticulitis usually presents as left lower-quadrant abdominal constant pain. When the sigmoid is redundant it may cause suprapubic or even right lower-quadrant pain. Asian populations have a relatively higher incidence of cecal diverticulitis. On the other hand, laboratory tests are supportive in the diagnosis but are not sensitive or specific.

Diagnosis

CT scan of the abdomen with a sensitivity and specificity for the diagnosis of acute diverticulitis of 94 and 99 percent, respectively, is usually used to confirm the diagnosis. However, colonoscopy should be avoided in the acute setting due to the risk of perforation, and unless the patient has had a recent colonoscopy, it should be performed at least 6 weeks after remission of the diverticulitis to exclude the possibility of an underlying colorectal cancer [23].

In addition to being widely available, inexpensive, and avoiding radiation exposure, high-resolution ultrasound has comparable sensitivity and specificity for acute diverticulitis as compared with abdominal CT scan. Nonetheless, abdominal ultrasound is operator dependent and cannot exclude other causes of abdominal pain [23].

Recurrent Diverticulitis: Risk Factors

Readmission rate for recurrent diverticulitis ranges from 9 to 25% [6, 8, 11–13] (Table 2). After a follow-up of 4 years, El Sayed et al. [6], in an English study of over 65,000 patients managed nonoperatively for their first episode of diverticulitis, found the recurrence rate to be around 11.2%. Emergency and elective colectomy rates were 0.9 and 0.75%, respectively. Female sex, young age, smoking, obesity, and complicated initial disease were risk factors for readmission and emergency surgery.

On the other hand, around 14,000 Canadian patients who were treated nonoperatively as well were followed up for almost 4 years in a study by Li et al [8]. The readmission rate was 9% while emergency surgery and elective colectomy rates were 1.9 and 1.7%, respectively.

Risk factors associated with recurrence were younger age and the persistence of postoperative pain. In other studies, the likelihood of recurrence was affected by the severity of the initial episode and not by age at onset [9].

Conservative therapy is successful in keeping 30% of these patients completely asymptomatic after the first attack. However, in a population-based study that reviewed the records of 3,222 patients with acute diverticulitis with a 10-year follow-up, recurrent diverticulitis occurred after the index and second diverticulitis episodes in 22 and 55% of patients, respectively. Female gender and younger age were associated with higher recurrence rate [4, 7].

Furthermore, recurrences do not infer higher risk of complications compared to first episodes [9]. After surgery, new diverticula develop in the remaining colon in around 15% and roughly 2–11% will require repeat surgery [3, 10]. Historically, recurrence of diverticulitis after surgery has been in the range of 7–11% with an estimated risk of recurrence over a 15-year period of 16% [3]. Recent data from several observational studies revealed recurrence rates of 10–35% after a first episode of uncomplicated diverticulitis [2, 5, 7].

Treatment

Prophylactic colectomy was advocated after two attacks of uncomplicated diverticulitis and after one attack in patients younger than 40 years [16]. The main reasons for offering surgical resection of recurrent diverticulitis are (1) to prevent further attacks and improve quality of life, (2) to prevent potential complications such as colovesical fistulae or colovaginal fistulae, and (3) to prevent the potential risk of an emergency procedure resulting in colostomy formation. However, the advent of high-resolution CT scans to determine the severity of inflammation and the introduction of less invasive interventions for draining the infectious process have changed the approach a surgeon now takes. There is a move towards se-
### Table 2. Pearls of recurrent diverticulitis

| Topic                                                                 | Reference |
|----------------------------------------------------------------------|-----------|
| Diverticulitis occurs in 4% of patients with diverticulosis          | [22]      |
| Recurrent diverticulitis Rate after primary attack treated conservatively: 11–35% | [1–10, 13] |
| Readmission rate for recurrent diverticulitis 9–25%                | [6, 8, 11, 12, 38] |
| Recurrent diverticulitis after surgery 7–16%                        | [3, 38]   |
| 36% have ongoing abdominal symptoms after the first episode of diverticulitis | [11–13] |
| Persistence of post-operative symptoms is a risk factor for recurrent diverticulitis | [8]       |
| Severity of first episode is a risk factor for recurrent diverticulitis | [8]       |
| CT scan evidence of gas pockets and abscess formation is a risk factor for recurrence | [1, 14]   |
| Younger age is a risk factor for recurrence                         | [2, 4, 6–8, 14, 15] |
| Younger age is a risk factor for emergency colectomy/colostomy       | [2, 6]    |
| Diverticular disease in younger age is not more severe               | [15]      |
| Male gender is a risk for recurrent diverticulitis                   | [15]      |
| Female gender is a risk for recurrent diverticulitis                 | [4, 6, 7] |
| Family history of diverticulitis is a risk factor for failure of non-operative management | [7]       |
| Long segment of involved colon is a risk factor for failure of non-operative management | [7]       |
| Presence of retroperitoneal abscess is a risk factor for failure of non-operative management | [7]       |
| Complicated recurrence rate 3.9–5%                                   | [5, 7]    |
| Right-sided colonic diverticulitis not associated with recurrence    | [5]       |
| Surgery is recommended after 2 episodes of diverticulitis and after one episode in patients younger than 40 years | [16]      |
| Emergency surgery for diverticulitis is 0.9–1.9%                    | [6, 8]    |
| Elective colectomy for diverticulitis is 0.75–1.7%                  | [6, 8]    |
| Likelihood of recurrent diverticulitis increases with number of recurrences |            |
| Recurrences do NOT infer higher risk of complications compared to the first episode | [9, 30, 39, 40] |
| Elective resection carries a lower risk of persisting symptoms compared to conservative management | [11, 13, 42] |
| Overlap between post-diverticulitis symptoms and irritable bowel syndrome | [28]      |
| Risk of Hartmann’s procedure after one diverticulitis attack is 1 in 2,000 | [30]      |
| 18 elective colonic resections are needed to prevent one colostomy   | [30]      |
| 92% of recurrent cases were treated as outpatient                   | [41]      |
| 2% of recurrent cases ultimately needed surgery                      | [41]      |
| 90% of chronic smoldering diverticulitis benefit from surgery         | [43]      |
| 77% of chronic smoldering diverticulitis had complete resolution of symptoms after surgery | [25] |
| Comparable complication rate between Hartmann’s and Primary anastomosis with stoma formation | [45, 46] |
| Stoma reversal with primary anastomosis was higher than Hartmann’s procedure in grade III and IV Hinchey Diverticulitis | [45, 46] |
| Total sigmoidectomy is associated with lower recurrence              | [3, 47]   |
Recurrent Acute Diverticulitis: When to Operate?

The intention of elective surgery has been to reduce emergency procedures, the need to create stomas, and to reduce the risk of complicated recurrence [31–37]. Conversely, this was defied in recent years by Andeweg et al. [38] who had an estimated risk of recurrence of 16% over 15 years; this translates to 1 of every 6 patients risking a recurrence after resection. Moreover, recurrent diverticulitis did not imply a higher rate of emergency surgeries. Ritz et al. [9], in their retrospective cohort of more than 1,300 patients, found that free perforation occurred in 25, 12, 6, and 1% with their first, second, third, and thereafter episodes, respectively.

Others have even found that complication and colostomy rates were not higher after the fourth recurrence episodes as compared to surgery after the first episode [30, 39, 40]. In fact, in a study of 110 patients with acute diverticulitis, 18% had one recurrence and 6% had two recurrences over a period of 10.5 years; those who re-
curred were treated as outpatients in 92% of cases and ultimately only 2% needed surgery [41].

On the other hand, Morris et al. [42], in their systematic review of 80 studies, found that chronic pain develops in 20–35% of patients treated nonoperatively compared with 5–25% of patients treated surgically. Many other authors have noted in their practice that there is a group who presents with atypical symptoms or chronic symptoms. These features do not fit in with acute diverticulitis as inflammatory markers are often raised. It is difficult to differentiate this entity from irritable bowel syndrome or chronic pain syndromes. There is another entity called chronic smoldering diverticulitis. These patients do not have complicated diverticulitis yet suffer severely with symptoms. Boostrom et al. [43] showed that operating on chronic smoldering diverticulitis can benefit up to 90% of patients while Horgan et al. [25] found that 77% of patients with smoldering diverticulitis achieved complete resolution of their chronic pain after sigmoid resection. Operating on smoldering diverticulitis is for treatment of symptoms and not to reduce the recurrence rate, unlike the general trend where patients undergo surgery to prevent recurrent diverticulitis after nonoperative treatment of an episode of complicated diverticulitis. Furthermore, complicated diverticulitis carries a higher morbidity and mortality should a recurrent episode of diverticulitis occur [44].

Many randomized trials have studied the use of mesalamine in the treatment of diverticulitis. Results have been variable [31, 32]. Carter et al. [33], in a 2017 Cochrane systematic review and meta-analysis of seven randomized trials, found no evidence of the benefit of mesalamine for the prevention of recurrent diverticulitis. In another study, 117 patients with acute diverticulitis were randomized to received placebo, mesalamine, or mesalamine plus a probiotic for 3 months and were followed up for 9 months. Mesalamine appeared to have lower symptom scores compared with patients who received placebo [31]. It is postulated that mesalamine may, therefore, have a role in conservatively managing patients with recurrent diverticulitis in the future.

**Surgical Approach**

Elective surgery for diverticular disease is generally delayed at least 6 weeks after the episode so that the inflammation and infection extensively resolve. Unfortunately, emergency surgery cannot be postponed in some situations, and in these cases the magnitude of intraperitoneal contamination dictates the choice of reconstruction. The Hinchey classification is widely used to assess the degree of contamination. Grade I is used for a small confined pericolic or mesenteric abscess. Grade II is for a larger abscess often confined to the pelvis. Grade III is for perforated diverticulitis, ruptured abscess, and/or purulent peritonitis. Last, grade IV is for ruptured diverticulitis with fecal peritonitis. Generally, with localized contamination – grades I and II – primary anastomosis without a protective ostomy can be performed, while with more diffuse contamination – grades III and IV – a two-staged procedure is generally preferred. The two-staged procedures are either a Hartmann’s procedure or a primary anastomosis with a protective proximal diverting stoma (Fig. 1).

Sixty-two patients with acute left-sided colonic Hinchey III and IV from 4 centers were randomized to Hartmann’s procedure or primary anastomosis with diverting ileostomy. The overall complication rate for both resection and stoma reversal operations was comparable. The stoma reversal rate after primary anastomosis with diverting ileostomy was higher. Serious complications, operating time, hospital stay, and in-hospital costs were significantly reduced in the primary anastomosis group [45].

Similarly, 102 patients with Hinchey grade III or IV diverticulitis randomly assigned to primary anastomosis or Hartmann’s procedure were studied in the DIVERTI
Recurrent Acute Diverticulitis: When to Operate?

French trial. The difference in the mortality and morbidity rates was insignificant. However, at 18 months of follow-up the primary anastomosis patients were more likely to revert their stomas (96 vs. 65%). Of note, receiving a protective stoma was at the discretion of the surgeon, whereby two-thirds of patients in the primary anastomosis group ended up receiving a protective stoma and one-third did not. Morbidity in the stoma subgroup was higher, but this result was likely biased since, in the subgroup that did not receive a stoma, all but one had grade III Hinchey diverticulitis [46].

**Surgical Margins**

Surgical margins have been investigated as well and it was found that total sigmoid colectomy with rectal anastomosis was associated with lower recurrence [3, 47]. In fact, Thaler et al. [47] found that colocolonic anastomosis with preservation of the distal sigmoid colon had a 4-fold risk of recurrent diverticulitis compared with colorectal anastomosis. Because the transverse and descending colon hardly ever have recurrence, it is unnecessary to resect all the diverticula-containing colon and thus any proximal soft and nonedematous colon segment is generally acceptable as a proximal margin [3]. On the contrary, the extent of resection and type of anastomosis were not important factors for recurrence in the study by Andeweg et al. [38].

Open surgery versus laparoscopic approach was assessed in a meta-analysis of 19 nonrandomized studies. The meta-analysis included 1,014 patients in the elective laparoscopic resection arm and 1,369 patients in the open arm. Open surgery was associated with significantly higher rates of wound infection, blood transfusion, postoperative ileus, and incisional hernia. This difference is highlighted in the short-term outcomes; however, long-term outcomes are comparable [48].

In the Sigma trial that included 104 patients with Hinchey I and II diverticulitis, laparoscopic approach was associated with longer operating time but less pain, improved quality of life, shorter hospital stays, and 15.4% reduction in major complication rates. The conversion rate was 19.2%, and the mortality rate was 1% [49]. However, in 2017 a Cochrane review that included this study found no superiority of one technique over the other [50].

Bowel obstruction, peritonitis, sepsis, and fistula were complications independently associated with mortality if they occurred after the first episode of diverticulitis. In addition, elective surgery carried a considerably lower mortality rate compared to emergency surgery for the recurrent episode. Recurrent attacks of acute diverticulitis carry the risk of gradual scarring and fibrosis with the sequela of forming a stricture.

Diverticular disease rarely causes complete obstruction. This allows either bowel preparation or on-table lavage to be done and in turn permits primary anastomosis. On the other hand, in their systematic review, Jones et al. [34] found that endoluminal self-expanding stents caused more cases of perforation, stent migration, and recurrent obstruction in benign colorectal obstructions compared to stenting malignant cases. However, these stents when used as a bridge to elective surgery avoided stoma in 43% of patients with diverticulitis [51].

**Special Consideration**

Immunosuppressed patients are especially predisposed to develop acute diverticulitis (0.02 vs. 1%) and, if they do, have a higher necessity to undergo emergency surgery (10–25 vs. 40%). Moreover, they have a higher mortality should they be operated on in an emergency (5 vs. 30%) [52, 53]. Furthermore, because of their immunosuppressed state, these patients often have atypical presentation and diagnosis is often delayed; therefore, they usually have a more severe acute diverticulitis and higher likelihood of perforation [54]. Hence, many surgeons offer elective surgery after resolution of the first attack of diverticulitis. However, these patients are often not cleared for surgical intervention and, therefore, recommendations on surgical intervention should be individualized based on their general health status. Concerning HIV-positive patients, lower CD4+ counts carry a poorer prognosis after surgery [54].

**Conclusion**

Studies in the literature have shown a highly variable approach in managing this group of patients. There is no well-defined evidence-based protocol that includes indication, timing, and method of surgery. Individualizing cases is the trend in dealing with these patients. Weighing the risk of developing chronic pain from conservative management versus the low probability of needing surgical intervention together with the advent of dependence on procedures performed by interventional radiologists to treat complicated diverticulitis is essential in gearing towards a certain treatment modality. Special attention should be paid to patients who are young and of female gender as they carry a higher risk of recurrence, in addition to the group of immunosuppressed patients who are...
still highly preferred to undergo elective surgical intervention to prevent the unfortunate complications which remain obscure until advanced stages in this subgroup of patients. Multicenter randomized controlled trials are needed to match the most beneficial treatment modalities with each patient subgroup.
