Abstract In fish, selenium can bioaccumulate and cause adverse impacts. One of the fish species potentially at risk from selenium in the San Francisco Bay (California, USA) is the splittail (Pogonichthys macrolepidotus). Previous studies have derived a whole body NOAEL and LOAEL of 9.0 and 12.9 mg/kg-dw, respectively, for selenium in juveniles. However, the NOAEL/LOAEL approach leaves some uncertainty regarding the threshold of toxicity. Therefore, the raw data from the original experiment was re-analyzed using a logistic regression to derive EC₁₀ values of 0.9 mg/kg-dw in feed, 7.9 mg/kg-dw in muscle, 18.6 mg/kg-dw in liver for juvenile splittail. Selenium concentrations in the dietary items of wild splittail exceed the EC₁₀ values derived here. Thus, deformities previously reported in wild splittail may have resulted from selenium exposures via the food chain.

Keywords Selenium · EC₁₀ · Splittail · Deformities

Selenium can bioaccumulate in aquatic organisms resulting in adverse effects when it exceeds threshold levels. In fish, these effects can include reduced production of viable eggs, post-hatch mortality, deformities in growing stages, and various pathological effects in the kidneys, liver, heart, and ovaries (Hamilton 2003, 2004; Lemly 2002). In severe cases, these effects may lead to population declines (Lemly 2002).

The San Francisco Bay (California, USA) receives inputs of selenium from several sources. The most important selenium loads are the Sacramento River (i.e., the dominant freshwater inflow to the bay during the wet season), agricultural drainage (via the San Joaquin River), local tributaries, and effluent from oil refineries, municipal wastewater treatment facilities, and other industrial facilities (Presser and Luoma 2006). Since there are several threatened and endangered fish species in the San Francisco Bay (Beckon and Maurer 2007), the potential for adverse impacts to those fish from selenium has generated substantial concern (Beckon and Maurer 2007; San Francisco Bay Regional Water Quality Control Board 2007). Additionally, the North San Francisco Bay has been identified as being impaired for selenium under Sect. 303(d) of
the Clean Water Act, and a total maximum daily load (TMDL) for selenium is under development (San Francisco Bay Regional Water Quality Control Board 2007).

Splittail (Pogonichthys macrolepidotus), a cyprinid native to the San Francisco Estuary, was listed as a threatened species between 1999 and 2003, and continues to be a species of special concern in the California Department of Fish and Game (Sommer et al. 2007). To examine the species of special concern in the laboratory. From this experiment, Teh et al. (2004) fed juvenile splittail organic selenium for 9 months in the feed, muscle, and liver, the data was analyzed using a logistic regression with maximization of Firth’s penalized likelihood function using the Newton–Raphson algorithm in XLSTAT 2008. The logistic regression is the most appropriate type of regression to use to analyze this type of data as the response is binary; i.e., animals were classified as either normal or deformed. The concentration data was logarithm (base 10) transformed prior to analysis.

Materials and Methods

Fish were maintained as described in Teh et al. (2004). Briefly, 7-month-old juvenile splittail (6.8 g average) were placed in 24 indoor flow-through (4 L/min) tanks (90 L each, 66 cm in diameter), with 40 fish randomly assigned to each tank. Water temperature was maintained at 23°C during the first 6 months of exposure but dropped to 18°C for the rest of the experiment.

The basal diet was described in detail in Teh et al. (2004). Torula and selenized yeast were added to the feed to create eight diets with the following selenium concentrations: 0.4 (no selenized yeast), 0.7, 1.4, 2.7, 6.6, 12.6, 26.0, and 57.6 (no Torula yeast) mg/kg-dw. Fish were fed twice daily (9:00 a.m. and 4:00 p.m.) with a daily feeding rate of 3% body weight (BW) in the first 5 months and adjusted to 2% BW/day for the remaining 4 months of the experiment. Each diet was randomly assigned to three tanks.

At the end of 9 months, five fish from each tank were randomly collected and sampled. The following data were collected for each fish: presence of deformities (yes/no), total length, body weight, and the concentrations of selenium in muscle and liver tissue. From these measurements, condition factor (i.e., CF, i.e., $100 \times \text{body weight (g)/[body length (cm)]}^3$) was calculated.

To determine if there was a relationship between the presence of deformities and the concentration of selenium in the feed, muscle, and liver, the data was analyzed using a logistic regression. Since the purpose of this analysis was to find the lowest concentration at which adverse effects occurred, only the prevalence of deformities in fish fed selenium at 0.4–6.6 mg/kg-dw were used in the re-analysis. At concentrations greater than 12.6 mg/kg-dw, the prevalence of deformities decreased (Table 1). However, body weight, total length, and condition factor significantly decreased at concentrations of 26.0 mg/kg-dw and greater (Table 1; Teh et al. 2004).

The probability of deformities increased with the concentration of selenium in feed (logistic regression, $-2\log(\text{likelihood}) = 60.41$, $r^2$ (Nagelkerke) = 0.32, Akike’s Information Criterion (AIC) = 66.41, df = 73, $p = 0.002$), muscle (logistic regression, $-2\log(\text{likelihood}) = 56.12$, $r^2$ (Nagelkerke) = 0.39, AIC = 62.12, df = 73, $p = 0.0004$), and liver (logistic regression, $-2\log(\text{likelihood}) = 55.00$, $r^2$ (Nagelkerke) = 0.31, AIC = 61.00, df = 69, $p = 0.005$). The equations for the probability of deformities from the best fitting logistic regression models are as follows:

$$P = \frac{1}{1 + e^{-(-2.02 + 2.47 \times \log_{10} [\text{Se in feed}] )}}$$

$$P = \frac{1}{1 + e^{-(-2.02 + 2.47 \times \log_{10} [\text{Se in feed}] )}}$$
Using these equations, 1, 5, 10, and 20% effect concentrations were calculated for selenium in feed, muscle, and liver from the data produced by Teh et al. (2004) (Table 2). The EC10 values predicted using the logistic regression were below both the NOAEL and LOAEL determined by Teh et al. (2004) of 2.7 and 6.6 mg/kg-dw in feed; 10.1 and 15.1 mg/kg-dw in muscle; and 23.0 and 27.0 mg/kg-dw in liver, respectively.

In the calculation of the EC10, the three highest dietary selenium concentrations (i.e., 12.6, 26.0 and 57.6 mg/kg-dw) were excluded. In these three concentrations, the prevalence of deformities steadily decreased (Table 1) from the highest prevalence of deformities that was observed at 6.6 mg/kg-dw. At the two highest concentrations, body weight, total length, and condition factor also significantly decreased (Table 1). Since the only adverse effect that was observed at the lower doses was deformities, the EC10 for deformities is protective of the other adverse effects observed in the experiment from exposures to dietary selenium; i.e., reduced body weight, total length, and condition factor. Further, since logistic regressions can only be used to examine straight line relationships, the highest three doses were excluded as the third to the highest dose represented an inflection point up to which the prevalence of deformities increased and after which it decreased.

The diet of splittail consists of bivalves (including Corbula fluminea and Potamocorbula amurensis), amphipods, cladocerans, harpacticoid copepods, mysids, and detritus (Moyle et al. 2004). In the San Francisco Bay, selenium concentrations in amphipods and mysids range from 1 to 3 mg/kg-dw (Stewart et al. 2004) and in the clams C. fluminea and P. amurensis selenium concentrations range from 2 to 9 and 5 to 20 mg/kg-dw, respectively (Stewart et al. 2004; Presser and Luoma 2006). These concentrations exceed the dietary EC10 of 0.9 mg/kg-dw (Table 2). Greenfield et al. (2008) reported mean selenium concentrations in the livers of adult splittail from three locations in the San Francisco Bay caught in 2001 and 2002. The average concentrations ranged from 8.36 ± standard deviation of 0.66 to 16.30 ± 1.83 mg/kg-dw. While the mean concentrations are all below the EC10 of 18.6 mg/kg-dw for livers, the 95th percentile for the

UCL95 95% Upper confidence limit, LCL95 95% lower confidence limit
location with the highest mean concentration is approximately 19.9 mg/kg-dw (calculated as mean ± 1.96 standard deviations). However, it should be noted that in the following year, the mean concentration at this location decreased to 8.84 ± 0.76 mg/kg-dw and that the EC₁₀ derived here is for juveniles. Nonetheless, given that selenium concentrations in the dietary items of splittail exceed the EC₁₀ for deformities, deformities may be expected in wild splittail, as has been reported by Stewart et al. (2004).

The NOAEL and LOAEL for deformities in juvenile splittail (Teh et al. 2004) are moderately higher than the U.S. Environmental Protection Agency (2004) proposed ALWQC of 7.91 mg/kg-dw (whole body). Converting the NOAEL, LOAEL, and EC₁₀ calculated here of 10.1, 15.1, and 7.90 mg/kg-dw (in muscle), respectively, to an equivalent whole body concentration using the equation from U.S. Environmental Protection Agency (2004) yields values of 9.0, 12.9, and 7.2 mg/kg-dw (whole body), respectively. While the NOAEL and LOAEL are greater than U.S. Environmental Protection Agency (2004) proposed ALWQC of 7.9 mg/kg-dw, the EC₁₀ is within the range of analytical error of the proposed ALWQC. However, it should be noted that the equation used to convert muscle concentrations to a whole body concentration was developed from data collected from bluegill. Therefore, the result calculated from the equation may not be accurate for other fish species (e.g., splittail).

The proposed ALWQC was based on a study conducted by Lemly (1993) using bluegill (Lepomis macrochirus). In a recent study designed to replicate Lemly’s (1993) experiment, McIntyre et al. (2008) exposed juvenile bluegill to three different combinations of selenium species and temperature. The calculated EC₁₀ values from the study ranged from 9.6 to 13.3 mg/kg-dw (whole body). These results are all greater than the proposed ALWQC and the EC₁₀ for splittail. Additionally, the results of McIntyre et al. (2008) indicate that differences in the experimental temperature regimes and selenium speciation can affect the toxicity of selenium and imply that further investigation of the effect of these factors on splittail may be warranted.
