ABSTRACT
We present high-precision transit observations of the exoplanet WASP-21b, obtained with the Rapid Imager to Search for Exoplanets instrument mounted on the 2.0-m Liverpool Telescope. A transit model is fitted, coupled with a Markov chain Monte Carlo routine, to derive accurate system parameters. The two new high-precision transits allow us to estimate the stellar density directly from the light curve. Our analysis suggests that WASP-21 is evolving off the main sequence which led to a previous overestimation of the stellar density. Using isochrone interpolation, we find a stellar mass of $0.86 \pm 0.04 M_\odot$, which is significantly lower than previously reported ($1.01 \pm 0.03 M_\odot$). Consequently, we find a lower planetary mass of $0.27 \pm 0.01 M_{\text{Jup}}$. A lower inclination ($87 \pm 4 \pm 0.3$) is also found for the system than previously reported, resulting in a slightly larger stellar ($R_s = 1.10 \pm 0.03 R_\odot$) and planetary radius ($R_p = 1.14 \pm 0.04 R_{\text{Jup}}$). The planet radius suggests a hydrogen/helium composition with no core which strengthens the correlation between planetary density and host star metallicity. A new ephemeris is determined for the system, i.e. $T_0 = 245 5084.519 74 \pm 0.000 20$ (HJD) and $P = 4.322 5060 \pm 0.000 031$ d. We found no transit timing variations in WASP-21b.

Key words: methods: data analysis – methods: observational – techniques: photometric – stars: individual: WASP-21 – planetary systems.

1 INTRODUCTION
Transiting planet systems are valuable because their geometry enables us to estimate accurate planetary properties. Time series photometry during the transit allows us to derive the orbital inclination and the relative radii of the host star and planet. Combining this with radial velocity variations and stellar parameters allows us to derive the absolute mass of the planet. Hence, the bulk density of the planet can be estimated with good accuracy, giving us insight into its composition (Guillot 2005; Fortney, Marley & Barnes 2007), thus placing constraints on planetary structure and formation models. Given the remarkable diversity in the structure of large planets, it is important to obtain planetary parameters which are as accurate as possible. However, obtaining high signal-to-noise ratio transit observations is difficult and consequently even some of the brightest stars with planets are lacking good-quality light curves and, hence, have poorly determined planetary parameters.

The Rapid Imager to Search for Exoplanets (RISE) instrument, mounted on the 2.0-m Liverpool Telescope (LT; Gibson et al. 2008; Steele et al. 2008), was designed for exoplanet transit observations. Its main scientific driver was the detection of transit-timing variations and hence the search for low-mass companions to ‘hot Jupiters’. RISE has a rapid readout frame transfer CCD and in $2 \times 2$ binned mode has a readout time of less than 1 s. This implies that for exposures longer than 1 s, dead time is negligible, substantially increasing the time on target. However, most exoplanet host stars are relatively bright and saturate the CCD for 1-s exposure. To avoid dead time losses, RISE observations are always defocused (e.g. Gibson et al. 2008; Joshi et al. 2009). Defocused photometry observations also have the advantage of spreading the point spread function over a larger number of pixels, thereby decreasing flat-fielding errors. RISE is therefore ideal for obtaining high-quality transit light curves for exoplanets.

WASP-21b is a Saturn-mass planet with $M_p = 0.30 \pm 0.01 M_{\text{Jup}}$ in a 4.3-d circular orbit (Bouchy et al. 2010). Its host star is a G3V type with $M_*=1.01 \pm 0.03 M_\odot$, $T_{\text{eff}} = 5800 \pm 100$ K and a low metallicity, $[M/H] = -0.4 \pm 0.1$. It was discovered by the SuperWASP-North survey (Pollacco et al. 2006) in its 2008–09 observing campaign. Bouchy et al. (2010) argue that WASP-21 is a member of the Galactic thick disc because of its low metal abundances, velocity relative to the Sun and age $\sim 12$ Gyr, which are similar to the thick-disc population. WASP-21b is among the lowest density...
planets, $\rho_p = 0.24 \pm 0.05 \rho_1$ (Bouchy et al. 2010), and has one of the lowest metallicity host stars. Therefore, its properties are particularly important for irradiation models. The current parameters of the system (Bouchy et al. 2010) are based on the SuperWASP discovery photometry and a partial transit light curve taken with RISE. However, the lack of a high-precision complete transit light curve required the assumption of the main-sequence mass–radius relation which tends to bias the estimate of the inclination. Furthermore, the age derived for WASP-21 is longer than the main-sequence lifetime of a 1.01 $M_\odot$ star. This suggests that WASP-21 could be evolved, which would invalidate the main-sequence assumption and bias the parameters of the system. To test the main-sequence assumption, we obtained further observations of WASP-21.

In this paper, we present transit observations of WASP-21b with RISE including a full transit light curve. Our high-precision light curves allow us to derive the planetary and stellar radii without assuming the main-sequence mass–radius relation for the host star. We describe our observations in Section 2. In Section 3, we discuss our transit model and present the updated parameters of the system in Section 4. Finally, we discuss and summarize our results in Section 5.

2 OBSERVATIONS

WASP-21b was observed with RISE (Steele et al. 2008) mounted at the auxiliary Cassegrain focus of the robotic 2.0-m LT on La Palma, Canary Islands. This is a focal reducer system utilizing a frame transfer e2v CCD sensor. The detector has a pixel scale of 0.54 arcsec pixel$^{-1}$ that results in a 9.4 $\times$ 9.4 arcmin field of view. RISE has a wide-band filter covering 500–700 nm which corresponds approximately to $V + R$. The instrument has no moving parts.

The LT has a library of flat-fields which are taken manually every couple of months. RISE flats are taken during twilight at different rotator angles so that there is a uniform illumination of the CCD. The exposure times of the images are automatically adjusted so that the peak counts in the individual flats are below the non-linearity limit of the CCD at 45 000 counts. Typically, the individual flats have between 20 000 and 40 000 counts. Due to the fast readout, we can obtain approximately 200 flat frames in a run; these are combined to create a master flat. For each observation run we use the master flat that is closest in time, although we note that these are very stable.

On 2009 September 09, we obtained a full transit of WASP-21b. A total of 6581 exposures in the $2 \times 2$ binning mode with an exposure time of 2.7 s were taken. The telescope was defocused by $-1.2$ mm which resulted in a full width at half-maximum (FWHM) of $\sim 11$ arcsec. For defocused photometry, the star profiles are not Gaussian. However, we found that, in our case, a Gaussian provided a good fit to the wings of the star profile, and could be used as a rough estimate of the profile width. Therefore, we estimated the FWHM in the usual way by cross-correlating a Gaussian profile with that of the star.

A second full transit observation of WASP-21b was attempted on 2010 November 24. In this case, deteriorating weather terminated the observations shortly after the mid-transit, by which time, 4008 integrations had been obtained. During these observations, the FWHM was $\sim 12.5$ arcsec.

Both data sets were reduced using the ULTRACAM pipeline (Dhillon et al. 2007) which is optimized for time series photometry. Initially, we bias-subtracted the data while we investigated systematic effects that were introduced by the flat-fielding process. We performed differential photometry relative to five comparison stars in the field, confirmed to be non-variable, and we sampled different aperture radii and chose the aperture radius that minimized the noise. For the first night, we used a 22-pixel aperture radius ($\sim 12$ arcsec), and for the second transit, a 32-pixel aperture radius ($\sim 17$ arcsec). The photometric errors include the shot noise, readout and background noises.

We also included in our analysis the previously published egress of WASP-21 taken with RISE (Bouchy et al. 2010). For consistency, we re-reduced the original data using the same method as for the other two observations. On 2008 October 07, 2220 exposures of 5-s duration were taken. We estimated a FWHM of $\sim 2.7$ arcsec; therefore, the level of defocusing was lower than in our observations. The best aperture radius was found to be 15 pixel ($\sim 8$ arcsec). Our results agree well with the previous published light curve.

The final high-precision photometric light curves are shown in Fig. 1 along with the best-fitting model described in Section 3.3. We overplot the model residuals and the estimated uncertainties which are discussed in Section 3.2.

2.1 Optimum exposure time for RISE

As mentioned above, defocusing is commonly used in exoplanet transit observations. Southworth et al. (2009) calculated the optimum exposure time for the Danish Faint Object Spectrograph Camera (DFOSC) imager mounted on the 1.54-m Danish Telescope. We follow the same procedure and apply it to RISE mounted on the
Figure 2. Light curve of the brightest comparison star for the 2009 September 09 observation relative to the ensemble of comparison stars used in WASP-21b final light curve. It shows systematic noise with an amplitude of 400 ppm. This comparison was not used in the final light curve of WASP-21. We also overplot the photometric errors.

LT, and hence, we account for readout noise, photon, background and scintillation noises. Similar to Southworth et al. (2009), we do not include flat-fielding noise, assuming that the profile position is stable.

The key difference is that RISE is a frame transfer CCD whose dead time is the frame transfer time, 35 ms for observations longer than 1 s. For the brightest comparison star in our field, \( (V \approx 9) \), we found the optimum exposure times with RISE are approximately 2.7, 7.8 and 10.8 s during bright, grey and dark time, respectively.

We iterate that the improvement in signal-to-noise ratio for defocused observations, reported by Southworth et al. (2009), is only due to dead time losses; hence, the defocusing needed is proportional to the CCD readout time. If the dead time was zero, then the best theoretical signal-to-noise ratio would always be for focused observations, mainly due to the increase in background noise for wider profiles.

Moreover, in our case, the improvement on signal-to-noise ratio between 1- and 10.8-s exposure times is quite small, of the order of 10 ppm per 30 s bin. As we will see below, the strongest reason for defocusing is to minimize systematic noise which, due to its nature, is not accounted for in the calculation and can substantially increase the noise in a transit light curve. Fig. 2 shows systematic noise variations larger than 400 ppm.

3 DATA ANALYSIS

3.1 Systematic noise

Exoplanet transit observations are often dominated by systematic noise. Therefore, to improve the precision of the light curves it is important to determine and minimize this noise source. For the 2009 September 09 observations, the brightest comparison star (c1) on the field was affected by systematic noise. This can clearly be seen in Fig. 2, where we show the flux of c1 relative to the ensemble of comparison stars used in the final 2009 WASP-21 light curve. This shows a variation of 400 ppm. We found that this systematic noise was correlated with the star position in the CCD, which during the transit observation varied by 10 pixels in the x direction and by 8 pixels in the y direction. Given that we used an aperture radius of 22 pixels, this implies that only half of the pixels used to perform aperture photometry were common for the duration of the observation. Hence, we concluded that the systematic noise was due to variations in the pixel-to-pixel sensitivity which were not corrected by flat-fielding. In fact, the systematic noise is slightly higher if we flat-field the data. Our master flat is a combination of 150 frames, each with a mean of 35 000 counts. The uncertainty in this flat is 0.5 mmag pixel\(^{-1}\), which is smaller than the photometric error (\(~4.4\) mmag per unbinned point) and the observed systematic noise. After careful analysis of the data, we found that the c1 comparison star crossed a reflection feature in the CCD that is rotator-dependent (LT is on an alt-azimuth mount) and thus was not corrected by flat-fielding. This experience demonstrates the importance of good guiding in decreasing the sources of systematic noise. If the observations were performed in focus and the seeing was 1 arcsec, then the FWHM would have been \(~2\) pixels. Using an aperture radius of \( 1.5 \times \text{FWHM} = 3 \) pixels, it would have implied that there were no common pixels during the observations. Therefore, we infer, if the observations were focused, the amount of systematic noise would have doubled. Note that the defocusing does not affect the guiding since the guide camera is always kept in focus.

After this incident, the RISE instrument was upgraded. The source of the reflected feature was identified and removed from the instrument field of view. We also improved the telescope guiding system’s stability. This led to an improvement in the precision of the light curves which is evident in the latest light curve of WASP-21 taken after the upgrades (see Fig. 1). In the 2010 November observations, the variation in position is less than 2 pixels in the x direction and 4 pixels in the y direction.

3.2 Photometric errors

An accurate estimate of the photometric errors is important to obtain reliable system parameters. Our first estimate of errors for each light curve includes only the shot noise, readout and background noises, which underestimates the true errors. To obtain a more reliable estimate, we begin by scaling the errors of each light curve so that the reduced \( \chi^2 \) of the best-fitting model is 1.0. This resulted in the multiplication of the errors by 1.97, 1.22 and 1.44 for the 2008, 2009 and 2010 light curves, respectively. We then calculated the time-correlated noise following the procedure from Gillon et al. (2009). Using the residuals of the best-fitting model, we estimated the amplitude of the red noise, \( \sigma_r \), to be 150, 250 and 150 ppm for the 2008, 2009 and 2010 light curves, respectively. These were added in quadrature to the rescaled photometric errors and were used in the final Markov chain Monte Carlo (MCMC) chains. However, Carter & Winn (2009) found that this ‘time-averaging’ method of estimating the correlated noise can still underestimate the uncertainties by 15–30 per cent.

3.3 Determination of system parameters

To determine the planetary and orbital parameters, we fitted the three RISE light curves of WASP-21b simultaneously. We used the Mandel & Agol (2002) transit model parametrized by the normalized separation of the planet, \( a/R_\ast \), ratio of planet radius to star radius, \( R_p/R_\ast \), orbital inclination, \( i \), and the transit epoch, \( T_0 \), of each light curve. Our model was originally developed to measure transit timing variations of exoplanets. Following Bouchy et al. (2010) that found no evidence for a significant orbital eccentricity of WASP-21b, we adopt a circular orbit. We included the quadratic limb-darkening (LD) coefficients for the RISE filter \( V + R \) from the models of Howarth (2011): \( a = 0.45451 \) and \( b = 0.210172 \). These were calculated for \( T_{\text{eff}} = 5800 \) K, log \( g = 4.2 \) and \( [\text{M/H}] = -0.5 \) to match the stellar parameters from Bouchy et al. (2010). We initially kept the LD parameters fixed during the fit. For each light curve, we included two extra parameters to account for a linear
normalization. Therefore, 12 parameters were fitted. Besides the linear normalization, no extra trends were removed from the light curve.

To obtain the best-fitting parameters and uncertainties, we used a MCMC algorithm (e.g. Tegmark et al. 2004; Collier Cameron et al. 2007; Gibson et al. 2008). We begin by calculating the $\chi^2$ statistic of a set of proposed parameters,

$$\chi^2 = \sum_{j=1}^{N} \frac{(f_j - m_j)^2}{\sigma_j^2},$$

(1)

where $f_j$ is the flux observed at time $j$, $m_j$ is the model flux and $\sigma_j$ is the uncertainty of each $f_j$ as described in Section 3.2. At each step in the MCMC chain, each proposed parameter is perturbed by a random amount which we call a 'jump function'. Each jump function is proportional to the uncertainty of each parameter multiplied by a random Gaussian number with mean zero and unit standard deviation. The new parameter set is accepted with probability,

$$P = \min\left(1, \exp\left(-\frac{\Delta\chi^2}{2}\right)\right),$$

(2)

where $\Delta\chi^2$ is the difference in the $\chi^2$ of subsequent parameters sets. Note, the new parameter set is always accepted if its $\chi^2$ is lower than the previous parameter set ($P = 1$). The jump functions are scaled by a common factor in order to ensure that 25 per cent of the steps are accepted, as suggested by Tegmark et al. (2004). To estimate the uncertainty of each parameter and calculate the jump functions, an initial MCMC fit was performed. With these jump functions, we computed seven MCMC chains each of 150,000 points and different initial parameters. The initial 20 per cent of each chain that corresponded to the burn in phase were discarded and the remaining parts merged into a master chain. We estimated the best-fitting parameter as the mode of its probability distribution and the $1\sigma$ limits as the value at which the integral of the distribution equals 0.341 per cent from both sides of the mode. We computed the Gelman & Rubin (1992) statistic for each fitted parameter and concluded that chain convergence was good.

To test how the LD coefficients affect the derived system parameters, we repeated the MCMC procedure by also fitting for the linear LD $a'$. This is the most sensitive to the observing filter. The quadratic LD coefficient, $b = 0.210\,172$, was kept fixed, because as reported by Gibson et al. (2008), the high precision of the RISE light curves is not enough to constrain the LD coefficients (i.e. the MCMC does not converge when fitting both coefficients). We restricted the linear LD coefficient to be the same for all the light curves since they were all taken with the same filter. Therefore, in the second MCMC procedure, we fitted 13 parameters. We estimated $a = 0.337 \pm 0.034$.

4 RESULTS

Comparing the fitted and fixed LD solutions, we concluded that although the fitted linear LD coefficient is statistically significantly different from the theoretical value, this does not affect the derived system parameters to any extent. The two solutions are within $1.5\sigma$ of each other. Contrary to what was found by other authors (e.g. Gibson et al. 2008; Southworth 2008), the uncertainties of the fitted LD solution are slightly smaller than those of the fixed solution. The $\chi^2$ of the fitted LD solution is similar to the fixed LD solution which does not justify the addition of an extra free parameter in the fit. Consequently, we conclude that our light curve is of insufficient quality to better constrain the linear LD relative to that achieved by theoretical models, and we choose to present the fixed LD solution.

The estimated transit times, combined the original ephemeris (Bouchy et al. 2010) were used to update the linear ephemeris,

$$T(\text{HJD}) = T(0) + EP.$$  

(3)

We found $P = 4.3221060 \pm 0.000031$ and $T_0 = 245.5084\,519\,74 \pm 0.000\,20$ which were set to the mid-transit time of the 2009 light curve. This ephemeris was used in the final MCMC procedures.

For future reference, the time residuals from the linear ephemeris are given in Table 1. We conclude that the time residuals of WASP-21b are consistent with a linear ephemeris.

The geometric system parameters of WASP-21 and the $1\sigma$ uncertainties derived from the MCMC analysis with fixed LD coefficients are given in Table 2. These parameters are directly measured from the transit light curve and are only weakly dependent on stellar properties through the LD coefficients. Note, all the derived parameters presented in Table 2 were calculated at each point of the chain. Therefore, the final derived values and errors were determined from their probability distribution as done for the fitted values. We obtain a significantly lower density than was previously reported in the discovery paper ($\rho_* = 0.84 \pm 0.09\rho_{\odot}$).

4.1 Stellar mass and age

To obtain the stellar and planetary physical properties, the geometric parameters have to be scaled with the stellar mass. The new high-quality transit light curves give a direct estimate of the stellar density. This allows a more accurate estimation of stellar mass than log $g$ derived from spectral analysis (Sozzetti et al. 2007). Currently, there are two main methods to derive the stellar mass from the stellar density. The first uses isochrones and mass tracks from stellar models (Sozzetti et al. 2007), and the second uses an empirical calibration derived from stellar eclipsing binaries (Enoch et al. 2010; Torres, Andersen & Giménez 2010).

Bouchy et al. (2010) derived the stellar mass through the empirical calibration between $T_{\text{eff}}$, $\rho_*$ and [Fe/H] (Torres et al. 2010) with the parametrization of Enoch et al. (2010). Following the same procedure, with the improved $\rho_*$, we derive a stellar mass of

| Table 1. Time residuals from the linear ephemeris. |
| --- |
| Epoch | Time residuals (s) | Uncertainty (s) |
| --- | --- | --- |
| −78 | 11 | 40 |
| 0 | −7 | 24 |
| 102 | 8 | 30 |

| Table 2. WASP-21 system parameters derived from the MCMC. |
| --- |
| Parameter | Value |
| Normalized separation a/R* | 9.68 ± 0.19 |
| Planet/star radius ratio R_p/R* | 0.10705 ± 0.00082 |
| Orbital inclination I (°) | 87.34 ± 0.29 |
| Impact parameter b (R*) | 0.458 ± 0.043 |
| Transit duration $T_{1-4}$ (d) | 0.1430 ± 0.0013 |
| Stellar density $\rho_*$ ($\rho_{\odot}$) | 0.652 ± 0.041 |
1.02 ± 0.05 M⊙. In Table 3, we present the mass and radius of WASP-21 and WASP-21b and the 1σ uncertainties derived from the MCMC for a stellar mass of 1.02 ± 0.05 M⊙. We obtain a significantly larger stellar and planetary radius than previously reported. This is due to the main-sequence assumption in the previous analysis which as discussed below is found to be invalid.

We also estimate the stellar mass from stellar models by interpolating the Yonsei–Yale (YY) stellar evolution tracks by Demarque et al. (2004) using the metallicity from Bouchy et al. (2010). These evolution tracks are plotted in Fig. 3 along with the position of WASP-21. From the isochrones, we estimate a lower mass of 0.86 ± 0.04 M⊙ and an age of 12 ± 2 Gyr for WASP-21. In Fig. 4, we also show the evolutionary tracks for stellar masses of 1.0, 0.95, 0.86 and 0.8 M⊙ adapted from Demarque et al. (2004). These suggest that WASP-21 is close to, or is already in, the hydrogen-shell-burning phase and hence is evolving off the main sequence. This implies that the assumption of a main-sequence mass-radius relationship in the original analysis of Bouchy et al. (2010) is faulty.

There is a significant difference between the mass derived from evolutionary models, $M_\ast = 0.86 ± 0.04$ M⊙, and the mass derived from the empirical calibration, $M_\ast = 1.02 ± 0.05$ M⊙. In the past, the Torres et al. (2010) calibration was found to be in agreement and a more straightforward alternative to the use of stellar models (Enoch et al. 2010; Torres et al. 2010). Moreover, it has the advantage that it can be directly included in a transit fitting procedure (Enoch et al. 2010). However, recently, the same discrepancy between empirical and isochrone masses was also found for WASP-37 (Simpson et al. 2011) and WASP-39 (Faedi et al. 2011). The Torres et al. (2010) eclipsing binary sample used for calibrating their relationship does not contain many low-metallicity systems, in particular in the low-mass regime. Therefore, this suggests that the Torres et al. (2010) calibration might not hold for metal-poor stars, especially in the low-mass regime. For these reasons, for WASP-21, we favour the lower mass derived from the evolution models. For a stellar mass of $M_\ast = 0.86 ± 0.04$ M⊙, we present the stellar and planetary radii for the WASP-21 system in Table 3 along with the 1σ uncertainties derived from the MCMC analysis.

To summarize, we derive a lower stellar mass, 0.86 ± 0.04 M⊙, and a lower planetary mass, 0.27 ± 0.01 M⊕. We estimate the inclination of the orbit to be 87.3 ± 0.3. The radius of the star is found to be 1.10 ± 0.03 R⊙, and the planet radius is 1.14 ± 0.04 R⊕, yielding a planetary density of 0.18 ± 0.02 $\rho_1$.

### 4.2 Eccentricity

Bouchy et al. (2010) found the eccentricity to be statistically indistinguishable from zero, i.e. the $\chi^2$ does not significantly improve when adding the two additional parameters to the circular model. For these cases, allowing the eccentricity to float tends to overestimate the eccentricity (Lucy & Sweeney 1971). Hence, Bouchy et al. (2010) adopted a circular orbit. Assuming a tidal dissipation parameter between $10^5$ and $10^6$, the circularization time-scale for WASP-21b is approximately between 0.017 and 0.17 Gyr, respectively. Since this is much shorter than the derived age for the system, we expect a circular orbit. However, if the orbit not circular, assuming a zero eccentricity results in underestimated uncertainties. Therefore, it is interesting to investigate the effect of a small non-zero eccentricity in the system parameters and their uncertainties. As an example, we assume an eccentricity of 0.04 ± 0.04, which is...
consistent with the discovery paper. We repeated the MCMC procedure allowing the eccentricity to float. Because the transit light curves do not constrain the eccentricity, we include a prior on the eccentricity of the form

$$\frac{(\text{ecc} - \text{ecc}_0)^2}{\sigma_{\text{ecc}}^2},$$

where we assume \(\text{ecc}_0 = \sigma_{\text{ecc}} = 0.04\). This prior is added to equation (1) at each step of the chain. From the posterior eccentricity distribution, we obtain an eccentricity of 0.038 ± 0.036, which is close to the input value.

The maximum effect of the eccentricity upon the derived parameters corresponds to the case where the transit occurs close to periastron (\(\omega = 90^\circ\)) or apastron (\(\omega = -90^\circ\)). Hence, in order to investigate the maximum deviation from a circular orbit, we assume \(\omega = 90^\circ\). For this particular case, by assuming a circular orbit we would be overestimating \(aR_\ast\), inc and \(\rho_\ast\), and underestimating the stellar and planetary masses and radii. The opposite would have happened if we have assumed \(\omega = -90^\circ\).

The derived eccentric solution is within 1\(\sigma\) of the circular solution, and the uncertainties of \(aR_\ast\), inc and \(\rho_\ast\), are ~30 per cent larger. This results in an increased uncertainty of ~30 per cent on the radii and ~20 per cent on the masses. Hence, we conclude that if the orbit eccentricity is <0.038, the system parameters would be within ~1.3\(\sigma\) of the values given in Tables 2 and 3.

5 DISCUSSION AND CONCLUSION

We have presented two high-quality transit light curves of WASP-21b taken with RISE. Together with the previous RISE partial transit, these were fitted with an MCMC procedure to update the parameters of the system. We have been conservative in our error estimates by scaling the \(\chi^2\) and by including time correlated noise in our analysis.

The derived stellar density, \(\rho_\ast = 0.65 \pm 0.05 \rho_\odot\), and the estimated age for the system, 12 ± 2 Gyr, suggest that WASP-21 is in the process of evolving off the main sequence. Therefore, the main-sequence mass–radius relation assumed for WASP-21 in the discovery paper was invalid, which led to a significant overestimation of the stellar density, thus affecting the derived planetary properties. Using the stellar models of Demarque et al. (2004), we derived a significantly lower stellar, \(M_\ast = 0.86 \pm 0.03 M_\odot\), and planetary mass, \(M_p = 0.27 \pm 0.01 M_{\text{Jup}}\). This lower host star mass somewhat compensates the lower stellar density which results in a stellar radius which is within 1\(\sigma\) of the one presented by Bouchy et al. (2010).

We obtained a slightly larger planetary radius, \(R_p = 1.14 \pm 0.04 R_{\text{Jup}}\), for WASP-21b than previously reported. Fortney et al. (2007) hydrogen/helium coreless models predict a radius of ~1.06 \(R_\odot\), which is consistent within 2\(\sigma\) with our estimated radius without the need for any extra heating mechanism. Following Laughlin, Crismani & Adams (2011), we compute a radius anomaly, \(\Delta R = 0.09\), for WASP-21b. This supports the correlation reported by Laughlin et al. (2011), i.e. \(\Delta R = T_{\text{eq}}^{1.4}\), where \(T_{\text{eq}}\) is the equilibrium temperature of the planet, which is ~1320 K for WASP-21b. Bouchy et al. (2010) argued that the density of WASP-21b strengthens the correlation between planetary density and host star metallicity for hot Saturns (Guillot et al. 2006; Burrows et al. 2007). With the addition of the latest Saturn mass planet discoveries (e.g. WASP-39, Faedi et al. 2011; WASP-40, Anderson et al. 2011), this correlation appears weaker. However, if we scale for the equilibrium temperature with, for example, \(\Delta R\), the correlation with metallicity is still strong (see fig. 6 in Faedi et al. 2011). Moreover, the correlation also holds for the more massive planets (see fig. 3 in Laughlin et al. 2011).

Exoplanet transit light curves are often affected by systematic noise that can in some cases dominate the photometric noise. Therefore, it is important to minimize the sources of systematic noise. In Section 3.1, we show an example of systematic noise present in our exoplanet transit observations and suggest that the first step to decrease this noise is to maintain the star in the same pixel position in the CCD during the observations. We confirm that defocused observations can also help in decreasing systematic noise, as well as in decreasing dead time losses, and hence improving the signal-to-noise ratio (Southworth et al. 2009). The systematic noise in our observations was due to the variation of the stellar position across the CCD.

ACKNOWLEDGMENTS

FKP is grateful to AWE Aldermaston for the award of a William Penny Fellowship. The RISE instrument mounted at the Liverpool Telescope was designed and built with resources made available from Queen’s University Belfast, Liverpool John Moores University and the University of Manchester. The Liverpool Telescope is operated on the island of La Palma by Liverpool John Moores University in the Spanish Observatorio del Roque de los Muchachos of the Instituto de Astrofísica de Canarias with financial support from the UK Science and Technology Facilities Council. We thank Tom Marsh for the use of the ULTRACAM pipeline. SCCB is grateful to Catherine Walsh for proofreading this paper and to Yilen GAmez Macqueo Chew for useful comments.
