1. Introduction

Exchange coupled ferromagnetic/antiferromagnetic (FM/AFM) bilayers [1, 2] have been intensively investigated mainly due to their technological applications in spin valves and magnetic tunnel junctions. In FM/AFM systems a particularly interesting and fundamentally important effect, namely the exchange-bias (EB) [3, 4] at the FM/AFM boundary, is manifested by the shift of the hysteresis loop and an increase of its coercivity. The magnetic properties of the exchange bias systems depend on the anisotropies of both the ferromagnet and the antiferromagnet. For this reason systematic experimental studies on systems, where strong and well defined FM anisotropy and exchange bias interaction coexist and interplay, are important.

We studied CoO/Fe(110) bilayers epitaxially grown on a W(110) single crystal substrate. In Fe(110) films on W(110), the magnetization rotates from the [1 1 0] to [0 0 1] in-plane direction above a critical thickness of spin reorientation transition (SRT) [5–7]. Such thickness-induced in-plane SRT was shown to occur in variety of bilayers, such as Au/Fe(110), Ag/Fe(110) [8, 9] or Co/Fe(110) [10, 11] and Au/Co/Fe(110) [12]. Here we report on SRT and exchange bias in Fe(110)/W(110) films coated with a metal-oxide layer (i.e., AFM CoO). For this system, we have recently shown how a ferromagnetic Fe layer can be used to tailor the magnetic anisotropy of the antiferromagnetic CoO overlayer [13]. In the present report we extend this study and present temperature dependence of exchange bias in CoO(111)/Fe(110) bilayers. We complement conclusions described in Ref. [13] by showing a true bilateral nature of FM-AFM interaction. Specifically we show that depending on the orientation of the frozen CoO spins, that can be controlled either by remanent magnetic state of the Fe or by applied field cool procedure, it is possible to strongly modify the magnetic anisotropy field of the Fe(110) layer.

2. Experimental and results

The W(110) crystal cleaning procedure [14], applied in ultra-high vacuum (UHV) chamber, consisted of repeated annealing cycles in an oxygen atmosphere ($5 \times 10^{-8}$ mbar at $1200^\circ$C) and subsequent flash heating to $1800^\circ$C. We used molecular beam epitaxy (MBE) technique to grow wedged Fe(110) films on W(110) at room temperature. After the preparation, the Fe films with thickness $d_{Fe}$ ranging from 80 to 300 Å, were post-annealed at 675 K. Next, a 90 Å thick CoO adlayer was grown on the Fe(110) wedge-films by reactive deposition of cobalt at a temperature of 470 K and at an O$_2$ partial pressure of $5 \times 10^{-7}$ mbar. The low-energy electron diffraction (LEED) pattern from the surface of the CoO-covered Fe(110)/W(110) sample indicated a hexagonal CoO(111) surface structure throughout the underlying Fe film. The X-ray absorption spectroscopy (XAS) spectra, ex situ measured at the XAS end station of National Synchrotron Radiation Centre Solaris in Kraków, indicate a proper stoichiometry of such prepared CoO overlayer, as deduced from comparison of the measured XAS intensity peak structure with literature data [15], see Fig. 1.

The magnetic properties of the CoO/Fe(110) system were studied in situ, using the longitudinal magneto-optic Kerr effect (MOKE). In Fig. 2, we present magnetic hysteresis loops acquired at $T = 300$ K with MOKE, for selected Fe thicknesses: $d_{Fe} = 80$, 120, 150, 160, 170, 200, 250, and 300 Å. Up to $d_{Fe} \approx 150$ Å, square

Fig. 2. Room temperature magnetic hysteresis loops measured using MOKE (black open dots) for $d_{Fe} = 80–300 \text{ Å}$. Starting from $d_{Fe} = 160 \text{ Å}$ (d) hard axis hysteresis loops are compared with simulations (red solid lines). The external magnetic field $H$ was applied along the $[1\bar{1}0]$ direction in the Fe(110) plane. Magnetic anisotropy constants, $A$ and $B$, used for each particular simulation are given in corresponding insets.

In order to determine the in-plane magnetic anisotropy (MA) constants for CoO(111)/Fe(110) bilayer, we performed simulations of the hard axis magnetic hysteresis loops for the 160–300 Å range of $d_{Fe}$. We describe the magnetization reversal within the coherent rotation model. Simulated magnetic hysteresis loops are obtained from the minimization of the free enthalpy density, $G$, as a function of the external magnetic field, $H$:

$$ G = -\frac{K_{EB}}{d_{Fe} \cos(\Phi)} + A \cos^2(\Phi) + B \cos^4(\Phi) - M_s H \cos(\Phi), $$

where $M_s$ is the saturation magnetization (its value can be assumed to be bulk-like for such thick Fe films), $\Phi$ defines the orientation of the Fe magnetization with respect to the Fe $[1\bar{1}0]$ in-plane direction, and $K_{EB}$ is the CoO/Fe exchange-coupling constant. $A$ and $B$ are the second- and fourth-order effective MA constants, respectively. They can be defined in terms of the volume and surface MA contributions:

$$ A = \frac{K_{v,p} K_{s,p}}{d_{Fe}}, \quad (2) $$

$$ B = \frac{K_{v,pp} K_{s,pp}}{d_{Fe}}. \quad (3) $$

In Eqs. (2) and (3), $K_{v,p}$ and $K_{v,pp}$ are the second- and fourth-order volume constants of the in-plane MA, while $K_{s,p}$ and $K_{s,pp}$ denote their surface analogues [9]. Since all RT loops are practically hysteresis-less, in all simulated hysteresis loops presented in Fig. 2d–h (red solid lines) a global minimum of energy was found for each value of external magnetic field. At RT there is no EB interaction in the CoO/Fe bilayers, therefore $K_{EB}$ value was kept zero in all corresponding simulations. For each $d_{Fe}$, the values of $A$ and $B$ were tuned to obtain the best match between the simulated and experimental hysteresis curves. The dependence of $A$ and $B$ on the inverse of the Fe thickness ($1/d_{Fe}$) is plotted in Fig. 3.

Clearly, $A$ and $B$ constants follow a linear dependence on $1/d_{Fe}$. From linear regression fits, as presented in Fig. 3, we find $K_{v,p} = 12.5 \times 10^{4} \text{ J/m}^3$, $K_{s,p} = 1.5 \text{ mJ/m}^2$, $K_{v,pp} = -3.6 \times 10^{4} \text{ J/m}^3$, and $K_{s,pp} = -0.1 \text{ mJ/m}^2$. The $K_{v,p}$ and $K_{s,p}$ values determined here for CoO(111)/Fe(110) bilayers can be compared to their analogues that we have recently reported for uncovered Fe(110) grown in the same UHV system and using identical preparation conditions [10]. The volume contribution $K_{v,p}$ is significantly enhanced by CoO capping as compared to uncovered Fe(110) films.
Fig. 3. Inverse-thickness, $1/d_{Fe}$, dependence of the second- and fourth-order effective MA constants, $A$ and $B$, as determined from magnetic hysteresis loops simulations. Lines represent linear regression fits from which surface and volume contributions to $A$ and $B$ are determined, see text for details.

$(K_v, p = 10.60 \times 10^4$ J/m$^3$ [10]) and this can be interpreted in terms of additional epitaxial strain introduced at the CoO/Fe interface. Even more drastic change is observed for the surface contribution, which for uncovered Fe(110) is almost twice smaller (0.8 mJ/m$^2$ [10]) when compared to the present CoO/Fe study. To conclude this part, contrary to a decrease of the magnetic surface anisotropy (MSA) usually observed in the case of noble metal (Ag, Au) adlayers [9, 10] or adsorption of oxygen [9] or UHV residual gases, Co [10] and CoO (present report) are the capping layers that can be used to efficiently increase the in-plane MSA at the Fe(110) surface.

The temperature dependence of exchange bias, described here by the shift field of the magnetic hysteresis loop $H_{EB}(T)$, is presented in Fig. 4a for $d_{Fe} = 80$ Å. A close to linear dependence of $H_{EB}$ on temperature is observed and the blocking temperature of CoO(111) on Fe(110) can be estimated as $T_B \approx 270$ K. It should be noted that in our system exchange bias is present even without field-cool (FC) procedure, however, particular choice of magnetic field orientation during FC is crucial for the orientation of AFM frozen spins and consequently for the magnitude of the shift field $H_{EB}$. When the sample is cooled at remnant magnetic state, we find that the orientation of AFM frozen spins follows the local (thickness dependent) orientation of Fe magnetization, in agreement with our previous report [13]. In case of FC procedure, when FC magnetic field is parallel to the local easy axis of Fe layer, the corresponding value of $H_{EB}$ is the same like for the sample cooled at its remnant magnetic state. On the other hand, when the sample is cooled in magnetic field oriented along Fe in-plane hard axis and high enough to magnetically saturate the Fe layer, the orientation of AFM spins switches to direction parallel to the FM hard axis. In such a case the shift field increases when the orientation of AFM spins is parallel to the direction of magnetic field applied during magnetization reversal.

We also observe the impact of AFM unidirectional magnetic anisotropy on the uniaxial magnetic anisotropy of FM layer. For $d_{Fe} = 200$ Å, when the FC procedure is applied, the anisotropy field of the typical hard axis hysteresis loop changes very slightly with decreasing temperature, compare hysteresis curves at 300 K and at 184 K (FC) in Fig. 4b. This is because CoO spins are frozen along Fe[1−10] direction and do not support the intrinsic, [001] magnetic anisotropy of 200 Å thick Fe layer. Situation changes drastically when the sample is cooled
to 184 K at the remnant magnetic state of Fe. In this case, Fe which is magnetized along [001] direction freezes the CoO spins along Fe[001] direction which results in a strong enhancement of magnetic anisotropy field, see hysteresis curve marked with open squares in Fig. 4b.

3. Conclusion

We have studied the CoO(111)/Fe(110) bilayer epitaxial system and we report on its in-plane MA and temperature dependence of exchange bias interaction. The Fe thickness induced in plane SRT observed in the Fe(110) films covered with CoO has its critical thickness $d_{Fe} = 160 \pm 5$ Å depending on the temperature. The blocking temperature for 90 Å thick CoO(111) adlayer is found to be close to the bulk value of CoO Néel temperature. A true interplay between AFM (CoO) and FM (Fe) layers is observed, namely the orientation FM magnetization determines the easy axis of AFM layer, but on the other hand AFM frozen spins can be used to strongly increase the in-plane uniaxial magnetic anisotropy of the neighboring FM.
