Abstract

Modern deep neural networks (DNN) have demonstrated remarkable success in image recognition tasks when the test dataset and training dataset are from the same distribution. In practical applications, however, this assumption is often not valid and results in performance drop when there is a domain shift. For example, the performance of DNNs trained on clean images has been shown to decrease when the test images have common corruptions, limiting their use in performance-sensitive applications. In this work, we interpret corruption robustness as a domain shift problem and propose to rectify batch normalization (BN) statistics for improving model robustness. This shift from the clean domain to the corruption domain can be interpreted as a style shift that is represented by the BN statistics. Straightforwardly, adapting BN statistics is beneficial for rectifying this style shift. Specifically, we find that simply estimating and adapting the BN statistics on a few (32 for instance) representation samples, without retraining the model, improves the corruption robustness by a large margin on several benchmark datasets with a wide range of model architectures. For example, on ImageNet-C, statistics adaptation improves the top1 accuracy from 40.2% to 49%. Moreover, we find that this technique can further improve state-of-the-art robust models from 59.0% to 63.5%.

1. Introduction

In the past few years, deep learning has shown unprecedented performance in various vision tasks [6, 16, 26, 35, 27]. It is widely known that significant performance drop can occur when there is a distribution shift between the training dataset and test dataset [2, 5, 9]. For example, in autonomous driving [11], a model trained with a dataset collected under good weather conditions might fail when exposed to low-light night or uncommon conditions, such as fog or storm. The classifier model is also shown to be vulnerable to common corruptions [13], such as Gaussian noise. These common corruptions exist in natural setup, causing critical concerns for the need to evaluate and improve corruption robustness.

In domain adaptation [8, 9, 39], an unlabeled target domain dataset is exploited to improve the model generalization capability to target domain. Roughly speaking, the clean images and corrupted images can be seen as coming from different domains: clean (source) domain and corruption (target) domain, respectively. Despite this conceptual similarity between domain adaptation and corruption robustness, the community tends to treat them as two distinct issues: Domain adaptation usually has a predefined target domain with unlabeled dataset [8, 9], while corruption robustness normally does not assume such a predefined corruption type [19]. One straightforward solution to improve the corruption robustness is performing data-augmentation with corrupted images during training. The limitation of this solution is that a model trained on images of a certain corruption type might be vulnerable to another type of...
corruption. For example, it has been shown that a model trained with Gaussian noise augmentation increases the robustness against Gaussian noise, which is expected, while decreases the robustness against contrast and fog corruptions [13, 45].

Given the constraint that the corruption type is unknown during the training stage, we can still exploit the corruption type during the inference stage. It is reasonable to assume that the corruption variant will not change for a short period of time during inference. For example, in autonomous driving, the weather condition is highly likely to be stable at least in a short period of time in most cases, thus, the system can capture multiple unlabeled images to represent the current weather condition. With a few representation samples, it is meaningless as well as impractical to directly apply the general domain adaptation techniques for retraining to improve robustness. In domain adaptation, there is one line of work adapting the feature statistics instead of adapting the BN [24]. Among them, what is most applicable in the context of corruption robustness is adaptive batch normalization (AdaBN) which simply adapts the batch normalization statistics without the need to retrain the model [29].

BN [24] has been widely adopted in modern DNNs, for example, most (if not all) seminal classification models, such as ResNet [15], DenseNet [22], ResNeXt [44], use BN by default. Moving average is often applied over the training dataset to estimate the population statistics for inference [24]. This inevitably causes a statistics shift if the test sample is from corruption domain different from the clean domain where the statistics are estimated. As indicated in Figure 1, we investigate and find that such influence on the model performance can be at least partially mitigated by estimating and adapting the statistics with a few representation samples from the corruption domain. Our investigation suggests that the model robustness against corruptions can be significantly improved by applying this simple yet effective technique.

Our contributions are summarized as follows:

- We interpret corruption robustness as a domain adaptation problem, inspired by which we investigate the effectiveness of adapting BN statistics on model corruption robustness.
- On several benchmark datasets, CIFAR10-C, CIAR100-C, ImageNet-C, we demonstrate that simply adapting BN statistics can significantly improve the model corruption robustness.
- We show that the technique is also orthogonal to current SOTA methods that improve the corruption robustness. For example, the accuracy of SOTA method “DeepAugment + AugMix” can be improved from 59.0% to 63.5%.

2. Related works

2.1. Batch Normalization

BN was originally introduced to reduce the covariate shift for faster convergence [24]. In follow-up work exploring how BN improves optimization [56], it has been found that the covariate shift has little to do with fast convergence and BN does not reduce the covariate shift. Instead, the success can be attributed to BN smoothing the optimization landscape [56]. The success of BN has also been found to be connected to the decoupling of length and direction [28]. Even though the mechanism of how BN helps training remains not fully clear, the phenomenon that BN boosts the performance and convergence is empirically proven in a wide range of works [13, 22]. BN also has a regularization effect due to the mini-batch stochasticity and increases the model generalization capability [30]. However, a large batch size is required for BN, which limits its applications [1]. Layer normalization [11] attempts to address this issue by exploiting the channel dimension instead of the batch dimension. For the purpose of style transfer, instance normalization (IN) [40], which only performs normalization on the individual feature channel, has also been explored. Inspired by the interpretation in [23] that IN performs a form of style normalization, Batch-Instance normalization has been proposed in [34] for automatically learning to normalize only disturbing styles while preserving useful styles. More recently, Group normalization (GN) has been proposed to perform normalization with groups (G) of channels [42]. Except for the normalization dimension difference between BN and GN, another core differentiation is that the GN has the same normalization statistics in training and testing, while the normalization statistics can be different for BN.

2.2. Robustness against domain shift and common corruptions

In practice, the distribution shift occurs as a major concern [8, 13]. To address this concern, numerous works assume having access to unlabeled samples from the target domain and target towards bridging the gap between the source domain and target domain by applying the techniques of domain adaptation [8, 9, 39, 20, 21]. More recently, another line of work focuses on the model robustness to common corruptions [18]. Hendrycks et al. established rigorous benchmarks for image classifier robustness by introducing ImageNet-C which is a new version of ImageNet with common corruptions [18]. Benchmarking robustness on other applications [33, 25] has also been proposed, demonstrating the community’s interest in corruption robustness. To improve the corruption robustness, data augmentation can be one straightforward solution, however, the augmented model can not be generalized to other cor-
ruptions. For example, [13] has shown that augmentation with Gaussian noise improves the model robustness against Gaussian noise while reducing the robustness against contrast and fog corruptions [13]. Training on images with transformed style has been found to improve the corruption robustness [12]. AugMix has been proposed in [19] as a simple prepossessing method combining consistency loss for improving robustness to unseen corruptions. Recently, DeepAugment has been proposed to combine with AugMix achieving SOTA corruption robustness [17].

2.3. Aligning or Adapting feature statistics

The above methods of improving robustness to common corruptions often require training the model on a special dataset or adopting a specially designed augmentation technique. In domain adaptation, aligning or adapting feature normalization statistics, i.e., mean and variance, has been found beneficial for bridging the gap between source domain and target domain [37, 3]. Adaptive Batch Normalization (AdaBN), has been proposed in [29] showing that adapting the mean/variance with target domain images improves the performance on the target domain. In this work, we explore the effectiveness of adapting BN statistic with a few representation corruption samples to improve the corruption robustness. Somewhat surprisingly, we find that this simple technique can improve the performance by a significant margin.

3. Rectifying batch normalization for improving model robustness

3.1. Revisiting classical batch normalization

We briefly summarize how BN works in practice. For a certain layer in the DNN, the feature layers of a mini-batch are represented by \( \mathcal{B} = \{x_1, \ldots, x_m\} \). During training, BN performs normalization on this mini-batch as follows.

\[
\hat{x}_i = \frac{x_i - \mu_B}{\sigma_B} \cdot \gamma + \beta
\]

where \( \gamma \) and \( \beta \) denote the learnable parameters scale and shift, respectively. In the remainder of this paper, we ignore \( \gamma \) and \( \beta \) for simplicity, thus Eq. 1 can be simplified as

\[
\hat{x}_i = \frac{x_i - \mu_B}{\sigma_B}.
\]

For 2D images, the mean \( \mu_B \) and variance \( \sigma_B^2 \) for a feature layer \( x_i \) of spatial width \( W \) and height \( H \), are calculated as:

\[
\mu_B = \frac{1}{MWH} \sum_{i=1}^{M} \sum_{j=1}^{W} \sum_{q=1}^{H} x_{ij}q,
\]

\[
\sigma_B^2 = \frac{1}{MWH} \sum_{i=1}^{M} \sum_{j=1}^{W} \sum_{q=1}^{H} (x_{ij}q - \mu_B)^2.
\]

where \( j \) and \( q \) indicate the spatial position of the feature layer. BN works in different modes during training and test stage. During the training stage, the normalization depends on the mini-batch statistics to ensure stable training, while this dependency becomes unnecessary during the test stage. Thus, the population statistics are adopted to make the inference depend on the individual input in a deterministic manner. Empirically, this population statistics \( \mu_P \) and \( \sigma_P^2 \) are estimated over the whole training dataset through moving average. It is worth mentioning that \( \mu_B \) and \( \sigma_B^2 \) are almost the same as \( \mu_P \) and \( \sigma_P^2 \), thus, in general, there is no mismatch in the BN statistics during training and testing.

3.2. Interpretation of BN statistics: Style instead of content

The information of an image can be described through content and style information [10]. Instance Normalization (IN) [41] was introduced to discard instance-specific contrast information from an image during style transfer. For a feature layer its individual mean and variance can be computed as:

\[
\mu_i = \frac{1}{WH} \sum_{j=1}^{W} \sum_{q=1}^{H} x_{ij}q, \quad \sigma_i^2 = \frac{1}{WH} \sum_{j=1}^{W} \sum_{q=1}^{H} (x_{ij}q - \mu_i)^2.
\]

According to [23], \( FC_i = \frac{x_i - \mu_i}{\sigma_i} \) indicate the feature content inherent to the sample by performing a form of style normalization, namely \( \mu_i \) and \( \sigma_i^2 \). It has been shown in [23] that simply adjusting the mean and variance of a generator network can control the style of the generated images. BN normalizes feature statistics for a batch of samples instead of a single sample. Thus, BN can be intuitively understood as normalizing a batch of samples with different contents to be centred around a single style. With this understanding, the population statistics \( \mu_P \) and \( \sigma_P^2 \) represent the style information instead of the content information in \( x_i \). To verify this hypothesis, we measure the absolute difference for BN statistics under different network inputs. The BN statistics are calculated for a randomly selected layer. The statistics are either calculated for samples from the ImageNet test dataset (indicated by \( \mu, \sigma^2 \)), or its corruption variants corrupted through Gaussian noise (indicated by \( \sigma^2_c, \mu_c \)). We averaged the results over 100 batches and present them in Figure 2. Comparing different batches coming from the same distribution (either corrupted or uncorrupted) we observe that the BN statistics are very similar and do not deviate much, indicating that these batches indeed have similar styles despite different content. Comparing batches of clean samples and corrupted samples, a relatively greater difference can be observed in the BN statistics for the same or different content. Overall, these results suggest that BN statistics are mainly determined by the mini-batch style instead of their content.
Figure 2. Absolute distance between the mean (top) and variance (bottom) for either the same or different batches of clean or corrupted samples. The results are averaged over 100 measurements. The statistics were calculated for a randomly selected layer of ResNet50 pretrained on ImageNet.

3.3. Motivation for rectifying batch normalization

To motivate our approach, we first showcase the influence of input corruptions on the BN statistics. To measure the shift caused by corruptions, we treat each feature output as a vector and adopt the cosine similarity $\cos$ between the feature output of a clean batch and a corrupted one and finally average over the batch size. The more similar two feature layer outputs, the more close the $\cos$ value is to 1. A value of 0 indicates that the two feature outputs are maximally dissimilar.

In Figure 3 we visualize the cosine similarity for a standard model over 5 severity levels of Gaussian noise corruption (blue line). With increasing severity the cosine similarity decreases indicating a greater deviation of the two feature layer outputs. To demonstrate that this degradation can be mitigated by rectification of the BN statistics, we compute the cosine similarity between the feature layer output of the original model and a rectified model for corrupted input samples (see Figure 3 orange line). We observe that rectifying the BN statistics improves the cosine similarity values over all severity values. The results support our hypothesis that the performance degradation caused by corruptions can be attributed to the shifted style information induced through the corruptions. This observation motivates to rectify the BN statistic with a small number of samples to improve model robustness under corruptions.

In practice, it is not challenging to obtain a reasonably small number of representation samples. For example, in the scenario of autonomous driving, weather conditions can change from day to day but tend to be consistent over a shorter time-frame. Thus a system can capture a few images (without labels) after a significant change in the conditions.

Figure 3. Cosine similarity between different feature outputs for a ResNet50 (ImageNet). The blue line indicates the cosine similarity between feature outputs of clean and corrupted images evaluated on the not yet rectified model. The orange line shows the similarity between feature outputs of clean images and feature output of corrupted image evaluated on the rectified model.

4. Experimental Setup

ImageNet-C was proposed by [18] to benchmark neural network robustness against common corruptions. ImageNet-C has the same image content as that of the ImageNet validation dataset (1000 classes and 50 images for each class) but perturbed with various corruptions. Specifically, there are 15 test corruptions and another four holdout corruptions. Similar to [19], we evaluate on the 15 test corruptions. Each corruption type has 5 different severities ranging from 1 to 5. The authors proposed similar dataset for CIFAR10 and CIFAR100, termed CIFAR10-C and CIFAR100-C respectively.

To rectify the BN statistics we randomly select a batch of 32 representation samples from the corruption dataset of the respective severity. We calculate $\mu_B$ and $\sigma_B^2$ according to Eq. 3 and update the population statistics with them without a prior.

We evaluate the performance of rectifying the BN statistics on various models trained on the corresponding clean dataset. We evaluate a wide range of state-of-the-art models. Following Hendrycks et al. we adapt the corruption error as a metric

$$CE^f_c = \frac{\sum_{s=1}^{5} E^f_{s,c}}{\sum_{s=1}^{5} E^{AlexNet}_{s,c}}.$$  \hspace{1cm} (5)

The mean over the different corruption types results in the mean CE indicated by mCE from here on. Additionally we report the top1 accuracy (Acc), also averaged over the different corruption types. We indicate the metrics after adaptation with a star, i.e. mCE* and Acc* to differentiate from that before rectification. For the Acc metric the higher the better, while for the mCE the lower the better.
5. Experimental Results

5.1. Evaluation on CIFAR10-C and CIFAR100-C

First, we provide evidence for the effectiveness of our proposed method rectifying the BN statistics to increase corruption robustness on the CIFAR10-C and CIFAR100-C benchmark datasets. To showcase the general applicability of our approach we rectify the BN statistics on a variety of models. The results for CIFAR10-C and CIFAR100-C are reported in Table 1 and Table 2 respectively. We observe that rectifying the BN statistics improve the performance by a large margin. For both datasets rectifying the BN statistics results in significant improvement in terms of robustness is observed across all tested models. For CIFAR-10-C, the performance of most models is improved by 10% points. The lowest performance increase is observed on ResNet-20 and is still 5% points. Notably, ResNet-20 also exhibits the lowest initial robustness with an mCE of 106.4 indicating being less robust to corruptions than AlexNet, but with an mCE of 90.7 after rectification.

In the case of CIFAR100-C, a trend can be observed, that the models with higher capacity exhibit a higher initial accuracy and also show a higher performance increase after rectification of the BN statistics. In particular, WRN-28-10, ResNeXt-29 and DenseNet all enjoy a robust performance increase of more than 12% points while the relatively smaller ResNet-20, ResNet-56 and VGG-19 increase by 5% points. Overall, the CIFAR-C results suggest that rectifying the BN statistics results in a minimum accuracy increase of 5% points but more often 10% and higher. This suggests that rectification of BN statistics is a simple yet effective technique to boost model robustness against common corruptions.

Table 1. Evaluation results on CIFAR10-C

| Model     | Acc  | Acc*  | mCE   | mCE*  |
|-----------|------|-------|-------|-------|
| ResNet-20 | 68.2 | 73.0  | 106.4 | 90.7  |
| ResNet-56 | 70.7 | 81.4  | 98.5  | 63.0  |
| ResNet-18 | 73.9 | 84.3  | 87.9  | 53.0  |
| ResNet-50 | 74.0 | 83.1  | 87.4  | 57.6  |
| VGG-19    | 72.9 | 81.0  | 90.1  | 63.7  |
| WRN-28-10 | 78.4 | 86.8  | 73.1  | 44.5  |
| ResNeXt-29| 75.0 | 85.5  | 85.1  | 49.9  |
| DenseNet  | 76.7 | 87.6  | 80.3  | 42.4  |

Table 2. Evaluation results on CIFAR100-C

| Model     | Acc  | Acc*  | mCE   | mCE*  |
|-----------|------|-------|-------|-------|
| ResNet-20 | 38.9 | 44.5  | 96.1  | 87.4  |
| ResNet-56 | 43.8 | 48.0  | 88.5  | 81.9  |
| VGG-19    | 45.3 | 51.4  | 86.1  | 76.6  |
| WRN-28-10 | 53.0 | 65.3  | 74.1  | 54.8  |
| ResNeXt-29| 52.7 | 66.0  | 74.6  | 53.7  |
| DenseNet  | 52.9 | 65.8  | 74.5  | 54.2  |

5.2. Evaluation on ImageNet-C

Besides CIFAR, ImageNet is another commonly used benchmark-dataset to evaluate classification accuracy. As above, we adopt its corrupted version ImageNet-C to evaluate the performance of different benchmark models obtained from the torchvision repository. The results are presented in Table 3. The results show that a change in the BN statistics can also result in significant performance improvements up to more than 9%. Similar to the trend observed on CIFAR100-C, we note a trend that models of relatively higher-capacity (Wide Resnet, ResNeXt and DenseNet) exhibit a higher initial accuracy (higher than 47%) compared to the relatively smaller models. However, opposed to the trend on CIFAR100-C, the relatively smaller models show a greater performance improvement of 9% compared to that of relatively larger models.

Table 3. Evaluation results on ImageNet-C on torchvision models

| Model       | Acc  | Acc*  | mCE   | mCE*  |
|-------------|------|-------|-------|-------|
| VGG-19 (BN) | 36.4 | 45.9  | 80.5  | 68.8  |
| ResNet 18   | 33.7 | 42.1  | 83.8  | 73.5  |
| ResNet 50   | 40.2 | 49.0  | 75.5  | 64.5  |
| Wide ResNet 101 2 | 47.2 | 51.9  | 66.5  | 60.7  |
| ResNeXt 101 32x8d | 48.0 | 55.0  | 65.5  | 56.8  |
| DenseNet 161 | 48.4 | 55.1  | 65.3  | 57.0  |

5.3. Evaluation on state-of-the-art models

The above pretrained models are not optimized for improving the model robustness against common corruptions. We further test whether similar performance boost can be observed on models that are optimized for achieving state-of-the-art robustness. AugMix was proposed in [19] as a simple preprocessing method together with a consistency loss. Despite simplicity, it achieves competitive robustness against corruptions, outperforming other approaches by a large margin. More recently, the authors proposed to strengthen AugMix by combining it with DeepAugment, achieving state-of-the-art performance [17]. The adopted model architecture is ResNet50. The comparison results are shown in Table 4. Compared with the baseline (vanilla ResNet50), training with “AugMix” and “DeepAugment + AugMix” improves the corruption robustness by a large margin. Strikingly, we observe that adapting the BN statistics also improves the accuracy from 49.4% to 56.9% for “AugMix”. For the SOTA training method “DeepAugment + AugMix”, adapting the BN statistics can still non-trivially improve the accuracy from 59.0% to 63.5%. Similar robustness can also be observed for the metric of mCE.
Table 4. Evaluation results on ImageNet-C on state-of-the-art models

| Model       | Acc  | Acc* | mCE   | mCE* |
|-------------|------|------|-------|------|
| Baseline    | 40.2 | 49.0 | 75.5  | 64.5 |
| Augmix      | 49.4 | 56.9 | 64.0  | 54.7 |
| Deepaug. + Augmix | 59.0 | 63.5 | 52.4  | 46.8 |

5.4. Evaluation on adversarially trained models

We further evaluate whether adversarially trained models [14, 32] can also benefit from rectifying the BN statistics. For evaluation, we use the publicly available robust ResNet-50 models for CIFAR10 and ImageNet from [7]. The models were adversarially trained with adversarial examples either bounded through an $L_2$ or $L_\infty$ norm with an upper bound of $\epsilon$ for a pixel range in $[0, 1]$. For the robustified CIFAR-10 models, it can be observed that adversarial training alone already improves the initial robustness significantly. The two adversarial robust models achieve the highest accuracy among all CIFAR10 models. Rectifying the BN statistics additionally increases the corruption robustness. The performance increase on the robust CIFAR models still is 3% points, which are less compared to that observed on the standard CIFAR models. For the adversarially trained ImageNet models, we observe an opposite trend. For the scenario without BN statistics rectification, adversarially trained ResNet-50 models exhibit a lower corruption accuracy than the normal models. However, after the BN statistics rectification, the corruption accuracy increases by about 15%, which is more than that observed on adversarially trained CIFAR10 models.

Table 5. Evaluation results on CIFAR10-C (top) and ImageNet-C (bottom) on adversarially trained models.

| Model       | Acc  | Acc* | mCE   | mCE* |
|-------------|------|------|-------|------|
| CIFAR-10    |      |      |       |      |
| ResNet-50 ($L_2$ $\epsilon = 0.5$) | 83.6 | 86.6 | 50.8  | 43.8 |
| ResNet-50 ($L_\infty$ $\epsilon = 8/255$) | 79.2 | 82.3 | 64.5  | 57.6 |
| ResNet-50 ($L_2$ $\epsilon = 3.0$) | 30.8 | 46.8 | 87.3  | 68.4 |
| ResNet-50 ($L_\infty$ $\epsilon = 8/255$) | 23.4 | 38.0 | 97.1  | 79.8 |

6. Analysis and Discussion

6.1. Number of representation samples

In the preceding experiments, the BN statistics were rectified using only a single batch of 32 samples. To motivate this hyper-parameter choice, we provide an ablation study analyzing the influence of the number of representation samples on the robustness performance. The results are presented in Figure 4. A relatively low/high accuracy/mCE is observed using a small number (1 to 4) of representation samples, indicating that the captured statistics are not representative for the overall corruption dataset. A number of representation samples as low as 8 already leads to a sufficiently robust performance above 70%. Increasing the number of representation samples lifts the accuracy, with no further improvements above 32 representation samples.

Figure 4. Influence of the number of representation samples used for rectification on Acc (left) and mCE (right) for a ResNet-18 trained on CIFAR10. The results are averaged over all severities for Gaussian noise corruption.

6.2. Impact of mean and variance

Rectifying the BN statistics involves the manipulation of two parameters, namely the mean $\mu$ and variance $\sigma^2$. As an ablation, we study the influence of each parameter in isolation to investigate their contribution to BN rectification. We indicate the rectifiable parameter in the subscript of the metric, i.e. Acc$^*_{\sigma^2}$ reports the accuracy for which only the variance $\sigma^2$ was rectified and the mean ($\mu$) was fixed. The results for the two scenarios are reported in Table 6. For CIFAR rectifying the mean has only a marginal influence. The improvement is never more than 1%. Significantly greater improvement is observed when $\mu$ is fixed and only the variance $\sigma^2$ is rectified. For both, ResNet-20 and ResNet-56, with the rectified $\sigma^2$ in most cases a higher accuracy is observed than in the case of rectifying both parameters. For example, under the standard-setting ResNet-20 achieves an Acc$^*$ of 73.0%, while rectifying only the variance results in an Acc$^*_{\sigma^2}$ of 79.3, an additional improvement by 6.3% points. For ImageNet, however, such a phenomenon cannot be observed. Fixing any of the two parameters results in a decrease in accuracy to even lower values than the corruption robustness of the model without rectification. Overall, we find that for simple datasets like CIFAR10-C and CIFAR100-C, only adapting the variance is sufficient and can even lead to better performances while for a more complex dataset like ImageNet-C, rectifying only one parameter is detrimental and both, $\mu$ and $\sigma^2$ need to be adapted.

Figure 5 breaks down the accuracies before and after rectification as well as with only the rectifiable mean and variance for each corruption type. The overall beneficial effect of BN rectification can be observed on most corruption types. Significant improvements can be observed for Gaussian noise, shot and glass corruption. For the corruptions elastic, jpeg, snow, fog and brightness the BN rectification slightly decreases the performance. Figure 5 further illustrates well the increased performance by only adapting the variance (Acc$^*_{\sigma^2}$) and the detrimental effects of rectifying only the mean (Acc$^*_{\mu}$). However, it is striking that in the cases where BN rectification decreased the performance,
rectifying either the mean or the variance parameter results in a better corruption performance than rectifying the parameters in combination, while still achieving only values around the initial corruption robustness. Overall, viewing the corruptions individually paints a more nuanced picture and reveals a different interplay between the mean and variance parameters on a case by case basis.

6.3. Location of rectified parameters

In the following, we investigate whether the location where the BN statistics will be rectified in the network influences the performance. Therefore, we separate the network into three thirds and only rectify the BN statistics in one of the thirds (front, middle, end). The results are shown in Table 8. A trend can be observed that adapting the BN statistics in the first third of the network achieves the highest accuracies. However, overall most of the performance gains under corruption are worse than the ones where all statistics were adapted. ResNet-50 and VGG-19 are exceptions to this observation, achieving marginal better performance by only rectifying the first third of the BN statistics. Rectifying only the BN statistics in the final section leads to accuracies on par with the non-rectified models, indicating only a minor influence on the overall corruption robustness.

6.4. Effectiveness of BN rectification

By training a model on a training set augmented by a certain corruption, we can achieve a model robust to this particular corruption type. The performance of this model on the respective corruption evaluation dataset can be interpreted as an approximate of the upper bound for this certain corruption type. With such an “upper bound”, indicated by \( \text{Acc}_{UB} \) we are able to relate the performance improvement by rectifying the BN statistics. The performances of a ResNet-20 trained on various corruptions for severity 3 is shown in Table 7. As we have already observed in Figure 5, rectifying the BN statistics does not improve the performance on all corruptions. Consequently, for defocus, snow, brightness and jpeg we also observe a decrease in robustness here. However, it is striking that for these particular corruption types Acc is already relatively close to \( \text{Acc}_{UB} \). For example for brightness, the model without rectified BN statistics exhibits only a gap of 1% to the performance of a model trained on the corruption. In cases where rectifying the BN statistics leads to an improvement in corruption robustness, a relatively large gap between Acc and \( \text{Acc}_{UB} \) is noticeable. For example for the corruptions of Gaussian noise, shot, impulse glass, and motion the gap between \( \text{Acc}_{UB} \) and Acc is 25 ± 0.5%.

6.5. Comparison with other normalization techniques

We evaluate the effect of group normalization (GN) and instance normalization (IN) on the corruption robustness. We train ResNet-18 and ResNet-50 with the respective normalization technique on CIFAR10 and ImageNet and evaluate their corruption robustness. The results for CIFAR10 and CIFAR100 are shown in Table 9 and Table 10 respectively. For CIFAR10 the models utilizing GN and IN achieve a higher corruption robustness accuracy than the model with non-rectified BN statistics (73.9% for ResNet-18 with BN and 74.0% for ResNet-50 with BN). ResNet-50
Table 7. Comparison of the performance of a ResNet-20 trained on various CIFAR10-C corruptions of severity 3 (AccUB), the corresponding rectified version of a standard trained model (Acc*) and the accuracy of a standard model on the respective corruption.

| Gaussian Noise | Shot | Impulse | Defocus | Glass | Motion | Zoom | Snow | Brightness | Contrast | Pixelate | Jpeg |
|----------------|------|---------|---------|-------|--------|------|------|-----------|---------|----------|------|
| AccUB          | 87.55| 88.42   | 91.46   | 91.70 | 87.55  | 90.38| 90.90| 90.04     | 91.59   | 91.57    | 90.70|
| Acc*           | 62.26| 63.74   | 66.40   | 83.01 | 62.48  | 75.55| 78.89| 70.40     | 82.64   | 80.62    | 77.90|
| Acc            | 33.41| 46.31   | 59.17   | 83.13 | 51.22  | 65.85| 71.75| 76.68     | 90.44   | 80.56    | 73.06|

Table 8. Evaluation of rectifying the BN statistics in different locations of the network. For this purpose we divide the network into three thirds. All experiments were conducted on CIFAR10-C.

| Model   | Front | Middle | End |
|---------|-------|--------|-----|
| Acc*    | mCE*  | Acc*   | mCE*|
| ResNet-20       | 71.7  | 95.7   | Acc*|
| ResNet-56       | 80.9  | 64.8   | 73.1|
| ResNet-18       | 83.1  | 57.2   | 72.5|
| ResNet-50       | 83.7  | 55.5   | 73.6|
| VGG-19          | 82.4  | 59.3   | 72.5|
| WRN-28-10       | 82.1  | 61.6   | 83.8|
| ResNeXt-29      | 83.8  | 56.2   | 78.3|
| DenseNet        | 86.0  | 48.2   | 79.2|

Table 9. Evaluation of CIFAR10-C on standard models trained on CIFAR-10 with normalizations other than BN on CIFAR-10.

| Model         | GN | IN |
|---------------|----|----|
| Acc           | mCE| Acc|mCE|
| ResNet-18     | 80.5| 66.3| 81.2| 64.2|
| ResNet-50     | 82.4| 60.4| 83.2| 57.6|

Table 10. Evaluation of ImageNet-C on standard models trained on ImageNet with normalizations other than BN.

| Model         | GN | IN |
|---------------|----|----|
| Acc           | mCE| Acc|mCE|
| ResNet-18     | 35.1| 82.2| 30.0| 88.8|
| ResNet-50     | 43.6| 71.5| 34.4| 83.1|

6.6. t-SNE analysis

In Figure 6 we visualize the feature vectors of 1000 randomly chosen images of a model without rectified and rectified BN statistics with t-SNE [31] in 2D. We observe that feature vectors produced by a network with rectified BN statistics are more clustered than the ones resulting from a model without rectified BN statistics.

6.7. Rectifying BN for adversarial perturbation

Regarding the model robustness, a parallel line of research analyses robustness properties of DNNs from an adversarial perspective. It was shown that small perturbations exist which are nearly imperceptible to the human eye and in combination with a clean sample are able to fool a neural network [38, 14, 4, 32]. Clean samples and adversarial examples have been shown to belong to two different domains [43]. Thus, we also experimented with rectifying BN statistics with the representative adversarial examples. However, this technique reduces instead of improving adversarial robustness, which suggests a significant difference between natural corruptions (average-case) and adversarial corruption (worst-case).

7. Conclusion

Motivated by the observation that features statistics can be interpreted as the style instead of the content, we proposed to rectify the BN statistics to improve model robustness against common corruptions. Despite simplicity, on several benchmark classification datasets with a wide range of seminal models, we demonstrate that simply replacing the BN statistics with those estimated from a few samples (32 for instance) can significantly improve the corruption robustness with an accuracy boost of around 10%. Moreover, our approach is orthogonal to the existing methods that achieve SOTA corruption robustness, and applying our approach to them results in a new SOTA performance. We also performed extensive analysis and found that (a) the performance boost increases with the increase of representation samples until it saturates near 32 samples; (b) variance adaptation is sufficient for CIFAR-C, while the more chal-
lenging ImageNet-C dataset requires adapting both mean and variance; (c) rectifying the front layers is more crucial than adapting the rear layers; (d) there is a significant im-

balance between different corruption regarding the performance boost; (e) other normalization like GN and IN have shown high corruption robustness on CIFAR-C and an op-

posite trend is observed on ImageNet-C; (f) Rectifying BN statistics also help to make the t-SNE more clustered, which provides some insight on the performance boost; (g) recti-

fying BN can not help improve the adversarial robustness, even though clean samples and adversarial samples can also be perceived to be from two different domains.
