Graphene, a 2D crystal bonded by π and σ orbitals, possesses excellent electronic properties that are promising for next-generation optoelectronic device applications. For these a precise understanding of quasiparticle behaviour near the Dirac point (DP) is indispensable because the vanishing density of states (DOS) near the DP enhances many-body effects, such as excitonic effects and the Anderson orthogonality catastrophe (AOC) which occur through the interactions of many conduction electrons with holes. These effects renormalize band dispersion and DOS, and therefore affect device performance. For this reason, we have studied the impact of the excitonic effects and the AOC on graphene device performance by using X-ray absorption spectroscopy on an actual graphene transistor in operation. Our work shows that the excitonic effect and the AOC are tunable by gate bias or metal contacts, both of which alter the Fermi energy, and are orbital-specific.

Graphene, a honeycomb network consisting of carbon atoms bonded by π- and σ-orbitals, is a model two-dimensional (2D) compound in physics1–3, electronics4–6 and chemistry7 due to its exceptional electronic properties, such as linear band dispersion1–4 and very high carrier mobilities2. A promising application of graphene is in optoelectronic devices8, such as mode-locked lasers9 and current-injection graphene terahertz lasers10, and this use requires an understanding of the behaviour of quasiparticles near the Dirac point (DP) in graphene11.

Many-body effects, such as electron-electron interactions, are prominent in graphene owing to a limited density of states (DOS) near the DP11, resulting in the enhancement of Coulomb interactions and reduced screening22. These effects significantly alter the behaviour of quasiparticles in graphene12, as manifested by the renormalization of the Fermi velocity13 and band structure14, and by excitonic effects in optical response15. Similarly, the behaviours of quasiparticles in bilayer graphene are altered also by many-body effects, such as excitonic effects16 and renormalizations of the Fermi velocity17 and phonon self-energy18. The many-body effects are tunable by varying the Fermi level EF12; they are enhanced near the DP, while they are weakened away from the DP. The position of the Fermi level varies with the key parameters for optoelectronic device operation, such as gate bias and metal contact properties19. The many-body effects are therefore likely to affect optoelectronic device performance.

An orbital-specific investigation is vital for the study of the many-body effects in graphene because they critically depend on the molecular orbitals involved. X-ray absorption spectroscopy (XAS) is a suitable tool for this as it can provide an element- and orbital-specific probe of electronic structure affected by dynamical many-body effects during the absorption processes, including excitonic effects20,21 and the Anderson orthogonality catastrophe (AOC)22,23. Although XAS has been applied to graphene24–27, XAS studies of a graphene device in operation have not yet been performed.

Here we present the results of microscopic XAS (μ-XAS) studies on an actual graphene transistor in operation. We demonstrate the orbital-specificity and tunability of excitonic effects and the onset of the AOC using gate bias or metal contacts, both of which alter EF.
Results

Effect of applying a gate bias. In the graphene device used in this work, bilayer graphene (see Supplementary Fig. S1) and Ni thin films were used as the channel and metal electrodes, respectively (see Fig. 1). The gate bias ($V_g$) was applied using a SiO$_2$ thin film as a capacitor and a Si substrate as a backgate. Under our experimental conditions, a negative gate bias means positive charging of graphene and therefore hole doping. The $\mu$-XAS spectra were acquired by using a photoemission electron microscope (PEEM) whose lateral resolution was 22 nm in the Auger electron yield mode.

Figure 1c shows $\mu$-XAS observations taken at the centre of the graphene for different values of gate bias. The $\mu$-XAS spectra are divided into two parts, consisting of $p^*$ ($\sim 285$ eV) and $s^*$ ($290–315$ eV) peaks. The $p^*$ peak is due to the excitation from the C1s core level into unoccupied states of the $\pi$ orbital, that is, the conduction band in graphene. The $s^*$ peaks are due to the excitations from the C1s core level to unoccupied $\sigma$ orbitals. The observed line shapes of the $\mu$-XAS spectra are similar to those of the spectra of bilayer graphene reported previously, thus confirming that our $\mu$-XAS measurements using the PEEM probed the electronic structure of the graphene in the device. The $p^*$ ($\sim 285$ eV) and $s^*$ ($\sim 307$ eV) peaks are strongly affected by changes in gate bias, as shown in Figure 1c. Although the $p^*$ peak position and intensity are both altered, the $s^*$ peak shows a change in only peak intensity. The $p^*$ peak position is redshifted by increasing the gate bias, as shown in Figure 2a. In a non-interacting system, the $p^*$ peak position is determined by the ground-state $\pi$ orbital without a core hole. The $p^*$ peak position should then be at 287.5 eV, which disagrees with our experimental value ($\sim 285$ eV). This discrepancy is due to the creation of an exciton, a pair consisting of many electrons and a core hole produced during X-ray absorption processes. According to the Nozières-deDominicis theory, the XAS intensity $A(\omega)$ follows a power law:

$$
A(\omega) \propto \left( \frac{1}{\omega - \omega_p^*} \right)^\alpha
$$

where the exponent $\alpha$ is governed by the AOC as well as the excitonic effect. The former, which reduces the intensity, is rationalized as follows. The initial state of the X-ray absorption processes consists of the core electron state and many conduction-electron states. In the final state, an electron is excited from the core electron state into one of the many conduction-electron states. The local potential induced by the core hole slightly alters the wave functions of all the conduction electrons, such that the initial and final states are orthogonal to each other. This means that the matrix element connecting the initial and final states tends to zero as the number of states approaches infinity. The contribution of the AOC to the exponent ($\alpha_A$) is thus given in terms of the DOS at $E_F$ as:

$$
\alpha_A \approx N_F V_0
$$

where $N_F$ and $V_0$ are the DOS at the Fermi level and the screened Coulomb interaction, respectively. Notably, the AOC is suppressed when $E_F$ is situated near the DP because of the vanishing of $N_F$, while it is recovered by moving $E_F$ away from the DP owing to the increase of $N_F$. The increased contribution of the AOC to the power law exponent as $E_F$ moves away from the DP thus accounts for the reduction of the $p^*$ peak intensity.

To scrutinize the orbital-specificity of the many-body effects, the change of the $s^*$ peak by the gate bias application is examined. As shown in Figure 1c and Figure 2a, the $s^*$ peak position is...
unchanged when varying the gate bias. According to a previous theoretical work\(^{29}\), the \(\pi^*\) excitation has been identified as a localized Frenkel-like exciton consisting of core hole and electron\(^{29}\), and hence experiences a significant peak shift. On the other hand, the higher-lying excitations such as \(\sigma_G^*\) peak are to delocalized conduction band states\(^{29}\), and are not affected by the excitonic effect not so much as the \(\pi^*\) excitation\(^{29}\). Hence, the invariance of the \(\sigma_G^*\) peak position is related with the absence of the excitonic effect for the \(\sigma_G^*\) orbital. It is therefore the ground-state unoccupied DOS (UDOS) without the influence of the core hole which is reflected in the line shape of the \(\sigma_G^*\) peak, in contrast to the \(\pi^*\) peak whose shape is determined by the excited-state UDOS with the influence of the core hole\(^{31}\).

Figure 2c shows the gate-bias dependence of the \(\sigma_G^*\) peak intensity. The intensity is enhanced by increasing the gate bias, in contrast to the depression of the \(\pi^*\) peak intensity (Fig. 2b). Because of the absence of the excitonic effect, the intensity enhancement must be attributed to a perturbation of the ground-state UDOS responsible for the absorption process in the \(\sigma_G^*\) peak. One candidate for this perturbation is the polarization of UDOS, which was suggested in a previous XAS study of an organic thin film transistor\(^{35}\). When polarization is induced, UDOS can undergo a change depending on the applied electric field\(^{35}\). As a result the polarization modifies the overlap of the core level and UDOS which determines the intensities of some of the components in the XAS spectra. In our work, the surface-normal component of the \(\sigma_G^*\) peak is larger than the surface-parallel component (see Supplementary Fig. S2). This surface-normal component of the \(\sigma_G^*\) orbital is perturbed by the surface-normal electric field produced by the gate-bias application, resulting in the enhancement of the \(\sigma_G^*\) peak. In contrast, the \(\pi^*\) peak is not significantly affected by this perturbation\(^{35}\). This could be due to the fact that the \(\pi^*\) peak is determined by the excited-state DOS with the core hole, while the \(\sigma_G^*\) peak is determined by the ground-state UDOS which is perturbed by the electric field. The above results for peak position and intensity indicate that, unlike the \(\pi^*\) orbital, the \(\sigma_G^*\) orbital is not strongly influenced by the many-body effects.

**Effect of contact with metal.** Carrier doping is also induced through contact with metal\(^{35,39}\); for example, contact with a Ni electrode induces hole doping in graphene\(^{39}\). Carrier doping leads to the formation of appreciably wide charge transfer regions due to the vanishing DOS near the DP, as suggested by previous reports on the performance of graphene transistors\(^{39}\). As demonstrated above, the many-body effects on the \(\pi^*\) peak are modulated by carrier doping through the application of a gate bias. Accordingly, the many-body effects on the \(\pi^*\) peak are also expected to be modified near the interface between graphene and a Ni electrode. Figure 3 shows that the \(\pi^*\) peak position near the interface exhibits a redshift due to hole doping, which is similar to the effect of varying the gate bias.

The orbital-specificity of the many-body effects due to the metal contact can be seen by considering the \(\sigma_G^*\) peak. Figure 3b shows that the \(\sigma_G^*\) peak position is not strongly affected by the presence of the graphene-Ni contact. This invariance indicates the absence of the excitonic effect just as it did when we varied the gate bias. Figure 4b shows the variation of the \(\sigma_G^*\) peak intensity near the graphene-Ni interface for different gate biases. Although the intensity is enhanced by applying a gate bias, the variation near the contact is less strong. The gate bias produces a stronger electric field across the SiO\(_2\) thin film (90 nm thick), in the order of 10 V/\(\mu\)m. On the other hand, our previous scanning photoelectron microscopy on graphene/SiO\(_2\)/Si in contact with Ni electrodes shows that the electric field near the contact is in the order of 0.1 V/\(\mu\)m\(^{34}\). This weaker electric field is ascribable to the reason for the smaller variation of the \(\sigma_G^*\) intensity. We have thus shown here that the contact of graphene with a metal produces an orbital-specific modulation of the many-body effects in a way similar to the application of a gate bias.

Figure 2 | Change of \(\pi^*\) and \(\sigma_G^*\) with gate bias. (a) Changes of \(\pi^*\) and \(\sigma_G^*\) peak positions with varying gate bias. (b) Reduction of \(\pi^*\) peak intensity with increasing gate bias. (c) Enhancement of the \(\sigma_G^*\) peak intensity with increasing gate bias.
Discussion

An important observation is that the $\pi^*$ peak position at the graphene-Ni interface is not pinned for different gate biases (see Fig. 4c). This behaviour is related to the so-called Fermi-level (de)pinning.

The $\pi^*$ peak position in the $\mu$-XAS spectrum of graphene is determined by the excitonic effect which is affected by $E_F$, as explained above. The variation of the $\pi^*$ peak position at the interface therefore indicates that the value of $E_F$ at the interface varies with gate bias.
This demonstrates that Fermi-level pinning, which has been controversial\textsuperscript{14}, does not occur under our conditions for fabricating the metal contact.

Also worth noting is how the redshift of the \( \pi^* \) peak near the interface, that is, in the charge transfer region, varies with gate bias. As can be seen in Figure 4c, the region where the redshift of the \( \pi^* \) peak varies near the contact is narrowed by the gate bias application. This narrowing of the charge transfer region is corroborated by considering that the screening length \( (\lambda) \), given by \( \lambda = [4\pi N_E]^{-1/2} \), decreases as \( N_E \) is increased by moving \( E_F \) away from the DF.

In conclusion, we have demonstrated that graphene possesses orbital-specific many-body effects, which vary with \( E_F \) through application of a gate bias or contact with a metal, by using \( \mu \)-XAS on an actual graphene transistor in operation. Since the many-body effects are involved dynamically in photoabsorption processes, our work is important for an understanding device characteristics, such as output characteristics of lasers and the energy distribution of emitted photons which is related to the (renormalized) DOS and band structure.

**Methods**

In this work, the device consisted of bilayer graphene, a SiO\textsubscript{2} thin film (90 nm thick) used as a capacitor, a p-Si(100) substrate used as the backgate and Ni thin film electrodes in contact with the graphene. The bilayer graphene was exfoliated from Kish graphite and transferred onto the SiO\textsubscript{2} thin film\textsuperscript{19}. The Ni electrodes were thermally evaporated onto the resist-patterned graphene in a chamber with a background pressure of 10\textsuperscript{−6} Pa and were subjected to a lift-off process in warm acetone. The gate bias was applied between the graphene and the Si backgate. The graphene in this work was positively charged so it could be doped with holes by applying a negative gate bias.

The \( \mu \)-XAS spectra were measured by the Auger electron yield method using a PEEM (LEEM III, Elmitec GmbH) installed at BL17SU at Spring-8\textsuperscript{3}. The DM-XAS spectra were corrected by using mirror current monitoring the incident x-ray intensity and the spectra of Cu(100) substrates taken just after the \( \mu \)-XAS measurement. The energy resolution of the incident X-rays (E/\( \Delta E \)) is better than 4,000\textsuperscript{39}. The lateral resolution of the \( \mu \)-XAS measurement, the incident X-rays were elliptically polarized unless otherwise noted. The \( \mu \)-XAS spectra are normalized by the intensity of the pre-edge region (around 278 eV).
