(Dated: January 20, 2013)

We perform a detailed analysis of all existing data (CELLO, CLEO, BaBar) on the pion-photon transition form factor by means of light-cone sum rules in which we include the NLO QCD radiative corrections and the twist-four contributions. The NNLO radiative correction together with the twist-six contribution are also taken into account in terms of theoretical uncertainties. Keeping only the first two Gegenbauer coefficients $a_2$ and $a_4$, we show that the $1\sigma$ error ellipse of all data up to 9 GeV$^2$ greatly overlaps with the set of pion distribution amplitudes obtained from nonlocal QCD sum rules—within the range of uncertainties due to twist-four. This remains valid also for the projection of the $1\sigma$ error ellipsoid on the $(a_2, a_4)$ plane when including $a_6$. We argue that it is not possible to accommodate the high-$Q^2$ tail of the BaBar data with the same accuracy, despite opposite claims by other authors, and conclude that the BaBar data still pose a challenge to QCD.

I. INTRODUCTION

The pion-photon transition $\gamma^* + \gamma^* \to \pi^0$ is an example par excellence of an exclusive process that can be adequately described within QCD by virtue of collinear factorization, provided both photon virtualities are sufficiently large (for a review, see [1]). Then, the transition form factor, defined by the correlator of two electromagnetic currents

$$\int \frac{d^4z}{(2\pi)^4} \epsilon^{\mu\nu\rho\sigma}(zP) \left| T \{ j_\mu(z) j_\nu(0) \} \right| 0 \right> \equiv \langle \pi^0(P) | T \{ j_\mu(z) j_\nu(0) \} | 0 \right> = i\epsilon_{\mu\nu\rho\sigma} q_\rho q_\sigma F^{\gamma^*\gamma^*\pi}(Q^2, q^2)$$

with $Q^2 = -q_\mu^2 > 0$, $q^2 = -q_\nu^2 \geq 0$, can be recast in leading-twist approximation in the convolution form [2, 3]

$$F^{\gamma^*\gamma^*\pi}(Q^2, q^2) = \frac{\sqrt{2}}{3} f_{\pi} \int_0^1 dx T(Q^2, q^2, \mu_F^2, x)$$

$$\times \varphi_x^{(2)}(x, \mu_F^2) + O(\delta^2/Q^4),$$

where the pion decay constant is $f_{\pi} = 132$ MeV, $\delta^2$ is the twist-four coupling, and where we assumed that the photon momenta are sufficiently large $Q^2, q^2 \gg m_{\pi}^2$. This way, the quark-gluon sub-processes, encoded in the hard-scattering amplitude $T$, can be systematically computed order-by-order within QCD perturbation theory. The binding (nonperturbative) effects are separated out and absorbed into a universal pion distribution amplitude (DA) of twist-two $\varphi_x^{(2)}(x, \mu_F^2)$, defined first in [4]. The variation of $\varphi_x^{(2)}(x, \mu_F^2)$ with the factorization scale $\mu_F^2$ is controlled by the Efremov–Radyushkin–Brodsky–Lepage (ERBL) renormalization-group evolution equation [2, 3]. This implies that the pion DA can be expressed in terms of the Gegenbauer polynomials $C_n^{3/2}(2x - 1)$ to read

$$\varphi^{(2)}(x, \mu^2) = \varphi^{as}(x) + \sum_{n=2,4,...} a_n (\mu^2) \psi_n(x),$$

where $\psi_n(x) = 6x(1-x)C_n^{3/2}(2x - 1)$ and $\varphi^{as}(x) = \psi_0(x) = 6x(1-x)$ is the asymptotic pion DA [2, 3].

The coefficients $a_n$ ($n \geq 2$) have to be determined within some nonperturbative model or be extracted from the data, taking into account evolution effects to account for their momentum-scale dependence. In most theoretical analyses they are derived from the moments $\langle x^n \rangle \equiv \int_0^1 dx (2x - 1)^n \varphi_x^{(2)}(x, \mu^2)$ with the normalization condition $\int_0^1 dx \varphi_x^{(2)}(x, \mu^2) = 1$.

A process with two photons of high virtuality cannot be easily measured experimentally. Experimental information is mostly available for an asymmetric configuration in which one of the photons is quasi-on-mass-shell with $q^2 \to 0$ [4, 5, 6]. In that case, perturbative QCD cannot be directly applied at a consolidated level because the real photon is emitted at large distances and has, therefore, a hadronic content which demands the application of nonperturbative techniques. Such a method is provided by light-cone sum rules (LCSRs) [5] (a recent application of this method to the pion-photon transition form factor is given in [6]) which augments QCD perturbation theory in approaching the real photon via a dispersion relation for $F^{\gamma^*\gamma^*\pi}$ in the variable $q^2$, keeping the large variable $Q^2$ fixed, viz.,

$$F^{\gamma^*\gamma^*\pi}(Q^2, q^2) = \int_0^\infty ds \frac{\rho(Q^2, s)}{s + q^2},$$

where the physical spectral density $\rho(Q^2, s)$ approaches at large $s$ the perturbative one:

$$\rho^{PT}(Q^2, s) = \frac{1}{\pi} \text{Im} F^{\gamma^*\gamma^*\pi}(Q^2, -s - i\varepsilon).$$

The resulting LCSR can be written as follows:

$$\int \frac{d^4z}{(2\pi)^4} \epsilon^{\mu\nu\rho\sigma}(zP) \left| T \{ j_\mu(z) j_\nu(0) \} \right| 0 \right> = i\epsilon_{\mu\nu\rho\sigma} q_\rho q_\sigma F^{\gamma^*\gamma^*\pi}(Q^2, q^2)$$

$$\times \varphi_x^{(2)}(x, \mu_F^2) + O(\delta^2/Q^4),$$

where $\rho(Q^2, s)$ is the physical spectral density, $s = Q^2 - q^2$. The systematical QCD analysis is done by taking into account radiative corrections and the twist-four contributions. The NNLO radiative correction together with the twist-six contribution are also taken into account in terms of theoretical uncertainties. Keeping only the first two Gegenbauer coefficients $a_2$ and $a_4$, we show that the $1\sigma$ error ellipse of all data up to 9 GeV$^2$ greatly overlaps with the set of pion distribution amplitudes obtained from nonlocal QCD sum rules—within the range of uncertainties due to twist-four. This remains valid also for the projection of the $1\sigma$ error ellipsoid on the $(a_2, a_4)$ plane when including $a_6$. We argue that it is not possible to accommodate the high-$Q^2$ tail of the BaBar data with the same accuracy, despite opposite claims by other authors, and conclude that the BaBar data still pose a challenge to QCD.

PACS numbers: 12.38.Lg, 12.38.Bx, 13.40.Gp, 11.10.Hi.
$Q^2 F_{\gamma^*\gamma^*}\left(Q^2\right) = \frac{Q^2}{m_0^2} \int_{x_0}^1 \exp\left(\frac{m^2 - Q^2 x}{M^2}\right) \bar{\rho}(Q^2, x) \frac{dx}{x} + \int_0^{x_0} \bar{\rho}(Q^2, x) \frac{dx}{x}$ \hspace{1cm} (6)

with the spectral density $\bar{\rho}(Q^2, x) = (Q^2 + s)\rho_{PT}(Q^2, s)$ and the abbreviations $s = xQ^2$ and $x_0 = Q^2/(Q^2 + s_0)$. The first term in (6) stems from the hadronic content of a quasi-real photon at low $s \leq s_0$, while the second one resembles its point-like behavior at higher $s > s_0$. The hadronic threshold in the vector-meson channel has the value $s_0 = 1.5 \text{ GeV}^2$, whereas $m_\rho = 0.77 \text{ GeV}$ \hspace{1cm} [10]. The Borel parameter $M^2$ entering the LCSR in (6) is not varied aiming to obtain the best stability of the LCSR. It is actually specified via $M^2 = M_{z,\rho}^2/\langle x \rangle_{Q^2}$ from the two-point QCD sum rule for the $\rho$-meson, where the corresponding Borel parameter is $M_{z,\rho}^2 \in [0.5 \div 0.8] \text{ GeV}^2$. Here, $\langle x \rangle_{Q^2}$ is some average value of $x$ at a fixed scale $Q^2$ in the integration region for the first integral on the r.h.s. of Eq. (6), i.e., $x_0(Q^2) < \langle x \rangle_{Q^2} < 1$—see also [8].

The remainder of the paper is organized as follows. In the next section, we review the current understanding of the experimental data on the pion-photon transition form factor, focusing on the problems related to the unestimated rise of the BaBar data [7] beyond 10 GeV². In Sec. II we present the salient features of a calculation of the pion-photon transition form factor using LSCRs with NLO accuracy and including the twist-four contribution. The results of our calculation are presented and discussed in detail in Sec. III, where a summary of our main findings is given in Sec. IV, where we also draw our conclusions.

**II. STATUS OF EXPERIMENTAL DATA**

Using the method of LSCRs with fixed $M^2 = 0.7 \text{ GeV}^2$, Schmidding and Yaklovlev (SY) [11] performed a next-to-leading order (NLO) QCD analysis of the data on $F_{\gamma^*\gamma^*}$, obtained by the CLEO Collaboration [8], with the inclusion of twist-four contributions, which they modeled by the asymptotic form, notably, [8] [12],

$$\varphi_\pi^{(a)}(x, \mu^2) = \left\{\begin{array}{ll}
\frac{80}{3} \delta^2(\mu^2) x^2(1 - x)^2 & \text{if } a = 0 \text{ and } a_4 = 0
\end{array}\right.$$

The major outcome of their analysis was that the best agreement with these high-precision data can be achieved by a pion DA with the coefficients $a_2^{SY}(\mu_{SV}^2) = 5.76 \text{ GeV}^2 = 0.19$, $a_4^{SY}(\mu_{SV}^2) = -0.14$, which after evolution to the reference scale $\mu_1^2 = 1 \text{ GeV}^2$ [13] become $a_2^{SY}(\mu_1^2) = 0.27$, $a_4^{SY}(\mu_1^2) = -0.22$.

At the same time, the asymptotic pion DA and the Chernyak-Zhitnitsky (CZ) model [14] with $a_2^{CZ}(\mu_1^2) = 0.56$ and $a_4 = 0$ were found to be outside the 2σ level. Later, this type of analysis was refined in [13] by taking into account the correct ERBL evolution of the pion DA to each measured momentum, including also the variation of the twist-four coupling $\delta^2 = \delta^2(\mu_1^2) = 0.19 \pm 0.04 \text{ GeV}^2$ in (7). This way it was shown that the DAs $\varphi^{\pi}_{\pi}$ and $\varphi^{CZ}_{\pi}$ are outside the 3σ and 4σ error ellipses, respectively, while the best fit yields $\chi^2_{\text{ndf}} = 0.47$ (where ndf denotes the number of degrees of freedom), see for more details in [13].

Even more important is the fact that the 1σ error ellipse of the CLEO data strongly overlaps with the admissible values of the coefficients $a_2$ and $a_4$, determined before in the framework of QCD sum rules with non-local condensates (NLC SRs) [17]. In particular, we proposed a “bunch” of admissible pion DAs with the central point $a_2^{BMS}(\mu_1^2) = 0.20$ and $a_4^{BMS}(\mu_1^2) = -0.14$ (termed the BMS model) that turns out to be within the 1σ error ellipse of the CLEO data [6]. These pion DAs (and similar ones obtained by two of us (BP) in [18] [19] by employing an extended version of the Gaussian model of the nonlocal QCD vacuum) have a distinctive feature: their endpoints at $x = 0$ and $x = 1$ are strongly suppressed—even relative to the asymptotic pion DA. This suppression is due to the finite virtuality $\lambda_2^2 = \langle \bar{q}q \sigma_{\mu\nu}G^{\mu\nu} \rangle/2(\bar{q}q) = (0.4 - 0.5) \text{ GeV}^2$ of the vacuum quarks, which enters the NLC SR for $\varphi_\pi^{(2)}$ in terms of the various condensate contributions (more details can be found in [17] [20]).

These findings remain valid even if one assumes a much stronger contribution from the twist-four pion DA, as estimated in [13] using the renormalon model [21] (see also [22]). The calculation of $F_{\gamma^*\gamma^*}$ beyond the NLO was carried out in [22] by taking into account that part of the next-to-next-to-leading order (NNLO) correction that is proportional to the first coefficient $\beta_0$ of the $\beta$ function, known from the earlier work in [24]. It turns out that this radiative correction is negative, thus providing suppression of the form factor at the level of about 8%, slowly decreasing with increasing $Q^2$. To the extent that one’s ambition is to comply with the CLEO data on $\gamma^*\gamma^* \rightarrow \pi^0$, it is mandatory to have a pion DA that has

1 The value of $a_2^{CZ}$ was originally determined by Chernyak and Zhitnitsky at the (low) scale $\mu_{SV}^2 = 0.25 \text{ GeV}^2$ [14] and reads $a_2^{CZ}(\mu_{SV}^2) = 2/3$. Its determination at the usual reference scale $\mu_1^2 = 1 \text{ GeV}^2$ is described in App. B of Ref. [13].

2 Here and below we denote by 1σ ellipse (ellipsoid) a confidence region in the $(a_2, a_4)$ plane that represents a coverage probability equal to 68.27%.
An increase of the form factor with \( Q \) contradicts the CLEO data which are well-described by endpoint-suppressed BMS pion DA (solid line in Fig. 1). Therefore, it came as a surprise that the data on \( \gamma\gamma^* \rightarrow \pi^0 \), presented by the BaBar Collaboration in 2009, indicate above approximately 10 GeV\(^2\) a marked growth of the form factor with \( Q^2 \) (see upper points (labeled by open crosses) in Fig. 1 taken from [23]). In fact, the BaBar Collaboration fitted their data with the expression

\[
Q^2 F_{\gamma^*\gamma\pi} \sim \left( \frac{Q^2}{10 \text{ GeV}^2} \right)^\beta,
\]

where \( \beta = 0.25 \pm 0.02 \), i.e., \( F_{\gamma^*\gamma\pi} \sim Q^{-3/2} \). This behavior of the form factor is incompatible with the collinear factorization and exceeds the asymptotic prediction considerably up to the highest measured momentum value just below 40 GeV\(^2\). Moreover, the high-\( Q^2 \) BaBar tail contradicts the CLEO data which are well-described by the dipole fit [2]

\[
Q^2 F_{\gamma^*\gamma\pi} \sim \frac{Q^2}{Q^2 + \Lambda^2}
\]

with \( \Lambda \approx 776 \text{ MeV} \). This scale behavior becomes more puzzling by comparing the \( \pi^0 \) BaBar data with the predictions extracted by the BaBar Collaboration from their analysis of the two-photon \( \eta \) and \( \eta' \) decays [22]—Fig. [4]. While the direct \( \pi^0 \) data grow with \( Q^2 \) and necessitate a wide DA with strong contributions from the endpoint regions \( x = 0, 1 \), the converted \( \eta - \eta' \) data are in perfect agreement with the prediction obtained with the endpoint-suppressed BMS pion DA (solid line in Fig. 1). To describe both sets of the BaBar data with the same accuracy looks like a catch-22-situation because it demands an impossible compromise for the structure of the pion DA (more on this and its implications later).

Many theorists have attempted during the past two years to explain the rise of the BaBar data using various schemes and drawing incongruent conclusions. We may group these theoretical proposals into four categories:

(i) Abandon collinear factorization
An increase of the form factor with \( Q^2 \) can be achieved by employing a flat-top pion DA, as proposed by Radyushkin [26] and by Polyakov [27]—which used, however, different schemes. The key element of these approaches is a nonvanishing pion DA at the endpoints \( x = 0, 1 \). Such a pion DA ascribes the rise of the large-\( Q^2 \) tail of the BaBar data to a logarithmic increase of

\[
(3/5)Q^2F_{\gamma\pi}(Q^2) \text{ (GeV)}
\]

FIG. 1: The \( \gamma\gamma^* \rightarrow |n\rangle \) transition form factor multiplied by \( 3/5 \) in comparison with \( Q^2 F_{\gamma\gamma^*\pi}(Q^2) \). The dashed line indicates the asymptotic limit for \( Q^2 F_{\gamma\gamma^*\pi}(Q^2) \). The dotted, dashed-dotted, and solid curves show the predictions from [15, 16] for the asymptotic, the CZ, and the BMS DA, respectively (figure taken from [23]).

the form factor induced by the flat-top DA. Note, incidentally, that as shown in [28], a ln \( Q^2 \) behavior can actually be imitated by including just the first three Gegenbauer polynomials without demanding the flatness of the pion DA. However, one has to pay a high price for this agreement: already the NLO contribution at the default normalization scale \( \mu^2 = Q^2 \) turns out to be huge for the flat-top DA, forcing a much lower normalization scale below \( \Lambda_{QCD} \) and making it virtually impossible to include evolution effects which are at the heart of QCD.

(ii) Deny rise of the form factor
Very recently, Agaev et al. [3] argued that the trend of the high-\( Q^2 \) tail of the \( \pi^0 \) BaBar data can be reproduced within QCD using LCSRs. Their analysis of the form factor includes radiative corrections at the NLO level, twist-four contributions, and, for the first time, a twist-six term which, though it has a positive sign, turns out to be small for their choice of the Borel parameter \( M^2 = 1.5 \text{ GeV}^2 \) to provide any serious enhancement.\(^4\) The distinctive feature of their models for the pion DA is a large and positive coefficient \( a_4 \) to which they attribute the rise of the form factor at high \( Q^2 \), while still higher coefficients \( a_n \) up to \( n = 12 \) have smaller values. The best agreement with the \( \pi^0 \) BaBar data is provided by a modified flat-like DA with \( a_2 = 0.13 \), which has a large tail of Gegenbauer coefficients, while the other two considered models are given by truncated expansions with

Note that at low momenta close to \( Q^2 \approx 1 \text{ GeV}^2 \), the twist-two contribution becomes comparable in size with the twist-four term.

\(^3\) This fact is emphasized by these authors as being rather crucial in selecting that large value of the Borel parameter.

\(^4\)
\(a_n\) up to \(n = 8\) and provide form-factor predictions that almost scale with \(Q^2\), but having a normalization exceeding considerably the asymptotic limit of \(\sqrt{2f_5}\). Even the model with \(a_n\) coefficients up to \(n = 12\), which become successively operative with increasing \(Q^2\), cannot simulate the increase of the form factor sufficiently well in comparison with the BaBar fit \(B\) used in \(B\)—provided one takes this fit seriously. At the same time, as one may appreciate from Fig. 1, all these models overestimate the form significantly. Taking into account the NNLO radiative corrections, would somewhat reduce the magnitude of the form factor by a few \% \(22\), but incorporating this effect would also shift the prediction further away from the \(\gamma^*\gamma \rightarrow \pi^0\) BaBar data—the main goal. Thus, the conclusion drawn in \(9\) that one may achieve simultaneous agreement with all data on \(F_{\gamma}\) using LCSRs within QCD seems rather perfunctory. At the same time, the fact that the twist-six term turns out to have a positive sign renders Chernyak’s recent claim in \(24\) that one can describe all data using the CZ DA supplemented by a power correction \(1/Q^6\) with a huge negative coefficient \((−1.2 \text{ GeV}^2)^2\) rather speculative.\(^5\)

(iii) **Contextual explanations**

Various authors (e.g., \(30\)) have presented calculations of \(Q^2 F_{\gamma}\) within the context of particular models—appealing, for instance, to the triangle anomaly—and have indeed obtained a logarithmic increase, emulating considerably the asymptotic limit of \(\langle \gamma^*_\gamma \rangle\). Taking into account the NNLO radiative corrections does not affect the results of our previous calculations within QCD and are specific for this particular process.

(iv) **\(k_\perp\) factorization**

Some authors try to explain the increase of the form factor by retaining the partonic \(k_\perp\) degrees of freedom unintegrated and employing a modified \(k_\perp\) factorization approach, see for instance \(31\). However, it is well-known from previous research \(32\) that Sudakov effects and \(k_\perp\)-generated power corrections give rather suppression than enhancement, albeit self-reinforcement is also possible \(31\). This subject is, however, outside the scope of the present investigation; it will be discussed in detail elsewhere.

### III. DATA ANALYSIS

The strategy of our investigation is to use LCSRs in order to process all available experimental data on the pion-photon transition form factor from different experiments \(B\), making some technical improvements relevant to our previous works in \(13\ 15\ 16\ 23\), and extending the analysis to the level of three Gegenbauer coefficients \(a_2, a_4, a_6\). The improvements and the applied algorithms are explained in detail below.

To compute the form factor, we employ the LCSR \(B\). In order to resolve the \(\rho\) and \(\omega\) meson resonances, we employ not a simple \(\delta\)-function ansatz, but a finite-width Breit–Wigner form \(3\ 23\). Adopting Khodjamirian’s general arguments \(8\), we relate the Borel parameter \(M^2\) in the LCSR \(B\) to the Borel parameter \(M_{\text{nf}}\) entering the two-point QCD sum rule for the \(\rho\) meson \(38\). Hence, instead of using the fixed value \(M^2 = M^2_{\text{nf}} = 0.7 \text{ GeV}^2\), as in our previous works \(15\ 16\ 18\ 14\ 23\), we write \(M^2(Q^2) = M^2_{\text{nf}}(\langle x \rangle_Q^2)\), where the average \(\langle x \rangle_Q^2\) is calculated by means of the Borel exponential \(\exp [Q^2 x/(M^2_{\text{nf}} x)]\) in \(17\). This prescription amounts to \(M^2(Q^2) \in [0.7±0.9] \text{ GeV}^2\).

The key ingredients of our data-analysis procedure are the following:

(i) The NLO gluon radiative corrections in the spectral density are taken into account using a corrected expression with respect to Eq. (3.12) in \(23\) which does not contain the error pointed out in \(9\). Note that this error does not affect the results of our previous calculations with LCSRs in \(13\ 15\ 16\ 23\). We adopt the so-called default renormalization-scale setting and identify the factorization and the renormalization scale with the large photon virtuality \(Q^2\). This avoids the appearance of (large) logarithms of these scales.

(ii) We take into account the twist-four contribution, allowing for a significant variation of the parameter \(\delta = 0.19 \text{ GeV}^2\) in the range 0.15 to 0.23 GeV\(^2\), referring the reader for a detailed discussion to our previous analysis in \(14\). As already mentioned, the use of a nonasymptotic form \(\phi_{\gamma^*\gamma}^{(3)}\) would not affect the results significantly \(13\ 22\). The parameter \(\delta^2(\mu^2)\) is evolved with \(\mu^2\) according to the one-loop renormalization-group equation, whereas other perturbative corrections to the twist-four contribution are ignored—expected to be small.

(iii) The evolution of the coefficients \(a_n\) is taken into account at the NLO level of accuracy using the QCD scale parameters \(\Lambda_{\text{QCD}}^{(3)} = 370 \text{ MeV}\) and \(\Lambda_{\text{QCD}}^{(4)} = 304 \text{ MeV}\), consistent with the NLO estimate \(a_n(M^2_{\text{nf}}) = 0.118 \ 10\).

(iv) The inclusion of the NNLO, radiative correction to the form factor, calculated in \(24\) and used in the spectral density in \(23\), as well as the twist-six term, computed for the first time in \(8\), are taken into account implicitly within the theoretical uncertainties. Their explicit evaluation is relegated to a future dedicated investigation. This treatment of the two contributions in terms of uncertainties is justified by the fact that for the average value of \(M^2(Q^2) \sim 0.75 \text{ GeV}^2\) the net result appears to be small, decreasing with \(Q^2\) from \(+0.005\) at \(Q^2 = 1 \text{ GeV}^2\)—where the twist-six term prevails—down to \(-0.003\) at \(Q^2 = 40 \text{ GeV}^2\)—where the NNLO correction becomes stronger. Note that in the calculation of the NNLO term only the convolution of the hard-scattering

\(^5\) However, other power corrections of different origin with negative sign cannot be excluded, but can hardly be accommodated within QCD.
amplitude $T_3$ with the asymptotic DA $\phi^{as}$ is taken into account (see for more details in [22]). It is worth mentioning that this behavior is sensitive to the choice of the Borel scale adopted in our work. Would we use instead the value $M^2 = 1.5 \pm 0.5$ GeV$^2$, advocated for in [9], then the twist-six term would be much smaller and the net result would be everywhere negative and almost constant: $\approx -0.004$.

IV. DISCUSSION OF RESULTS

To be able to make precise estimates of the influence of the high-$Q^2$ tail of the BaBar data on the form factors, we use two different data sets: one which collects all available data from three experiments [13, 14] for the $Q^2$ region between 1 and 9 GeV$^2$ (termed for convenience “CLEO regime”) and a second set which includes as well the high-$Q^2$ BaBar data up to about 40 GeV$^2$. These results are displayed in Fig. 2 left and right panel, respectively. In practice, this analysis procedure allows us to understand the role and relative strength of the coefficient $a_6$ in determining the characteristics of the 1$\sigma$ error ellipsoid of each data set selection, shown in this figure by its principal axes and corresponding ellipses.

The middle point $(0.17, -0.14, 0.12)$ of the 1$\sigma$ error ellipsoid in the left panel of Fig. 2 resulting from analyzing the data in the CLEO regime, corresponds to a rather good $\chi^2_{\text{ndf}} \approx 0.4$. This ellipsoid is stretched along the axis $a_6$ and has a sizable intersection with the $(a_2, a_4)$ plane, shown in the figure as a smaller ellipse inside the green rectangle. In contrast, the inclusion of the high-$Q^2$ BaBar data (right panel) forces the ellipsoid away from that plane to a new middle point $(0.18, -0.17, 0.31)$ with a worse value $\chi^2_{\text{ndf}} \approx 1$. Observe that the projection of the ellipsoid on the $(a_2, a_4)$ plane remains almost unchanged, while its middle point ▼ moves slightly away from its previous location, albeit it still resides inside the region of the negative values of $a_4$. The fact of the matter is that both error ellipses mentioned above cover a quite large region of those values of the coefficients $a_2$ and $a_4$ which have been determined in [17] with the help of NLC SRs—slanted (green) rectangle in Fig. 2. In particular, the position of the BMS pion DA in the $(a_2, a_4)$ plane is just inside both ellipses for the CLEO regime with respect to all data (left panel) and still inside the 2D projection when one takes into account also the BaBar data up to 40 GeV$^2$ (right panel).

To further quantify these considerations, we perform a more detailed data analysis with the focus on the $(a_2, a_4)$ plane and show the results in Fig. 3. The left panel refers to the data selection for the $Q^2$ values in the CLEO regime, while the right panel shows the analogous findings for the second case when we implement the analysis by including all BaBar data up to the highest measured value of $Q^2$. To this end, we calculate the 1$\sigma$ error ellipses by allowing the parameter $\delta^2$ to vary by 20% around the value 0.19 GeV$^2$. All ellipses obtained this way are then merged together into a single distorted 1$\sigma$ error ellipse shown in Fig. 3 for different situations. These are the following: The largest ellipse—dashed line in red color with the middle point ▼—represents the result of combining the projections on the plane $(a_2, a_4)$ of the 3D data analysis. The smaller ellipse (solid blue line) shows...
the analogous result of a 2D analysis by means of $a_2$ and $a_4$. Its middle point $\bullet$ with the coordinates $(0.15, -0.09)$ and $\chi^2_{\text{ndf}} \approx 0.5$, almost coincides with the middle point $\bullet$ of the area of values determined by NLC SRs. Finally, the smallest ellipse (thick line), entirely enclosed by the previous one, is obtained by combining the intersections with the $(a_2, a_4)$ plane of all ellipsoids generated by the variation around the central value of $\delta^2$. The ellipsoid which corresponds to the central value $\delta^2 = 0.19$ GeV$^2$ is shown in the left panel of Fig. 2.

The locations in the $(a_2, a_4)$ plane of some characteristic pion DAs are also indicated in Fig. 3, notably, the asymptotic DA ($\bullet$), the CZ model ($\blacksquare$), and also the projection of Model III from [9] (▲). It is worth emphasizing that the slanted (green) rectangle that contains those values of $a_2$ and $a_4$ derived from NLC SRs [17] lies almost completely within both larger error ellipses—greatly overlapping with the smallest one as well. In particular, the BMS model DA $\bullet$ turns out to be inside of all 1$\sigma$ error ellipses. Hence, the results of the 2D and 3D data analyses are in good mutual agreement, while we observe no tension between them and the theoretical predictions obtained from NLC SRs [17]—at least at the level of $\chi^2_{\text{ndf}} \leq 0.5$. What is more, all calculated 1$\sigma$ error ellipses are complying fairly well with the boundaries for $a_2$ provided by two independent lattice simulations. The older estimate from [39] is indicated in both panels of this figure by the vertical dashed lines, whereas the very recent results given in Ref. [40] (Table XII there) are denoted by the dashed-dotted vertical lines in blue color.

As one can see from the right panel of Fig. 3, the situation changes considerably when the high-$Q^2$ tail of the BaBar data [29] is included in the data analysis. Using the same designations as in the left panel, we show the analogous unified error ellipses, observing that now the ellipsoid has no intersection with the $(a_2, a_4)$ plane. Moreover, the composed error ellipse resulting from the 2D analysis (solid blue line) moves out of the region of the negative values of $a_4$ and inside its positive domain. This is accompanied by the significantly worse value $\chi^2_{\text{ndf}} \approx 2$, in sharp contrast to the value $\chi^2_{\text{ndf}} \approx 0.5$ we found for the data set in the CLEO-regime. On the other hand, the unified 1$\sigma$ error ellipse of the 3D projections on the $(a_2, a_4)$ plane (larger dashed red ellipse), keeps its position unchanged and still harbors a big portion of the area for the $a_2$, $a_4$ values, compatible with the results from NLC SRs (shaded rectangle in green color).

Comparison with the lattice findings shows that the 3D error ellipse lies almost entirely within the boundaries from [39] (dashed vertical lines) but intersects with the interval determined in [40] (dashed-dotted vertical lines) only for the larger values of $a_2$. The analogous ellipse of the 2D analysis only poorly complies with this small $a_2$ window of [40], whereas it partly overlaps with the low end of the $a_2$ range determined in [39]. Thus, the mutual agreement between the 2D and the 3D analysis, observed in the left panel, now deteriorates. Moreover, it becomes obvious from this figure that Model III from [9] has a projection on the $(a_2, a_4)$ plane that lies outside of all considered 1$\sigma$ error ellipses of the data. Note incidentally that selecting for the Borel parameter the value $M^2 = 1.5$ GeV$^2$, as used in [9], we find for their Model III an agreement with the BaBar data on the level of $\chi^2_{\text{ndf}} \gtrsim 1.5$.

This discussion becomes more substantiated by inspecting Fig. 4 which compares theoretical predictions with various experimental data with appropriate designations provided in the figure. Our calculations are displayed in the form of a shaded strip (green color) with a width reflecting various theoretical uncertainties. These are (i) uncertainties owing to the spread of the “bunch” of the pion DAs derived in [17], (ii) those originating from
the variation of the twist-four parameter $\delta^2$, and (iii) those related to the sum of the NNLO$_{D_0}$ term and the twist-six contribution [2]. Because these two latter contributions are comparable in size, they almost mutually cancel. For a more detailed understanding, we have compiled the calculated form-factor values for the BMS DA at each measured point in Table III (last column), including also the aforementioned theoretical errors. Note that the first error originates from items (i) and (ii), whereas the second one stems from item (iii).

As one clearly sees from Fig. 4 these predictions (shaded strip in green color), obtained with LCSRs within the standard collinear factorization scheme of QCD, cannot reproduce the significant rise of the high-$Q^2$...
tail of the $\gamma^*\gamma \to \pi^0$ BaBar data \cite{8}. But, surprisingly, they are in very good agreement with the BaBar data for the two-photon $\eta$ and $\eta'$ decays \cite{23} using the description of the $\eta - \eta'$ mixing in the quark flavor basis \cite{42}. These data are also shown in the fifth column of Table \ref{tab:table}. Under the assumption that the state $|n\rangle = (\bar{u}u) + |dd\rangle/\sqrt{2}$ has a DA similar to that of the pion, one can link the $\gamma^*\gamma \to |n\rangle$ transition form factor, multiplied by $3/5$, to the form factor $\gamma^*\gamma \to \pi^0$, where the prefactor arises from the quark charges. Strictly speaking, one should compare the state $\pi^0$ not with the physical particles $\eta$ and $\eta'$ but with the other neutral states $\eta_1$ and $\eta_8$ of the pseudoscalar meson sector. The observed discrepancy of the two BaBar data sets indicates that the structure of $\eta_8$ is very different from that of $\pi^0$, which looks implausible in view of the fact that both these states belong to the octet (a detailed discussion of this issue is given in \cite{32} and \cite{41}). Whether this is a true dynamical effect or accidental cannot be answered rigorously at present. One realizes from this figure that two BaBar data points for the $\gamma^*\gamma \to \pi^0$ measurement \cite{7} at $Q^2 = 12.7$ GeV$^2$ and 27.3 GeV$^2$ also lie inside the shaded strip, being perfectly in line with the data for the $|n\rangle$ form factor. Moreover, our predictions (shaded strip) approach, together with these data, the asymptotic QCD limit $\sqrt{2} f_\pi$ from below. In marked contrast, the predictions derived by Agaev et al. \cite{32}—single solid lines in this figure—fail to comply with these data and exceed considerably the asymptotic QCD limit. Unfortunately, they even fail to provide agreement with the $\gamma^*\gamma \to \pi^0$

BaBar data as well. Indeed, as one sees from Fig. \ref{fig:fig4} the characteristic rise of these data with $Q^2$ beyond 10 GeV$^2$ cannot be reproduced, mainly because the enhancement provided by a large and positive coefficient $a_4$ is not really sufficient—even augmenting it with the inclusion of some more higher coefficients $a_6$, $a_8$,...—so that the form factor gradually flattens out instead of increasing with $Q^2$. However, in view of the fluctuations of the BaBar data at higher $Q^2$ values, one cannot rule out a flatter behavior than the fit in Eq. (8) proposed by BaBar. To quantify the above statements and facilitate comparisons with other approaches, we collect in Table \ref{tab:table} the statistical properties pertaining to the data fits, using various sets of data and selected pion DA models. Let us also mention that the variation of the lower bound of $Q^2$ in the statistical analysis, e.g., the exclusion of the lowest five experimental points to prevent a strong influence of twist-4 uncertainty, does not affect the pattern of the $x^2_{\text{min}}$ values of the BMS DA, Asy DA and the CZ DA, shown in Table \ref{tab:table}. A detailed analysis of the variation of the lower bound in $Q^2$ has been given in \cite{16}.

Be that as it may, the most immediate conclusion is that the BaBar data for the pion and the $|n\rangle$ state seem antithetical and cannot be equally reproduced within the standard QCD scheme.

The accuracy of the experimental data on $\gamma^*\gamma \to \pi^0$ and the precision of current lattice simulations in extracting constraints on the second moment $\langle \xi^2 \rangle_\pi$ of the pion DA have both reached a level that can be used to determine the range of values of the next moment $\langle \xi^4 \rangle_\pi$, where both experimental data and lattice computations overlap. This possibility was first pointed out in \cite{43} and the following range of values was extracted from the 1$\sigma$ error ellipse of the CLEO data \cite{30} in conjunction with the lattice constraints for $\langle \xi^2 \rangle_\pi$ from \cite{14}: $\langle \xi^4 \rangle_\pi \in [0.095, 0.134]$ at $\mu^2_{\text{Lat}} = 4$ GeV$^2$ and for $M^2 = 0.7$ GeV$^2$. Here we refine this procedure in the following way: first, we map the $(a_2,a_4)$ plane onto the $(\langle \xi^2 \rangle_\pi, \langle \xi^4 \rangle_\pi)$ plane.

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{fig4.pdf}
\caption{(color online). Predictions for the scaled form factor $Q^2 F(Q^2)$ using a logarithmic scale for $Q^2$. The predictions using the BMS “bunch” of $\pi$ DAs are displayed in the form of a shaded (green) strip, with the solid line denoting the BMS model \cite{13}. The width of the strip contains various theoretical uncertainties explained in the text. The two single solid (blue) lines reproduce the predictions of Agaev et al. \cite{32} with their models I and III, whereas the prediction using their model II—not shown—would be in-between. (For the sake of comparison, we extended these predictions beyond 40 GeV$^2$ in the form of dashed lines up to the remote point of 112 GeV$^2$. The experimental data are taken from various experiments \cite{22} \cite{12} \cite{23} \cite{11}).}
\end{figure}

\begin{figure}[h]
\centering
\includegraphics[width=0.8\textwidth]{fig5.pdf}
\caption{(color online). Predictions for the moments $\langle \xi^2 \rangle_\pi$ and $\langle \xi^4 \rangle_\pi$ at the lattice scale $\mu^2_{\text{Lat}} = 4$ GeV$^2$. The solid (blue) ellipse corresponds to our choice of $M^2$, whereas the dashed (red) one results when using $M^2 = 1.5$ GeV$^2$. The vertical lines show the range of values computed on the lattice: dashed line—\cite{30}; dashed-dotted (violet) line—\cite{40}.}
\end{figure}
TABLE II: Statistical properties of selected pion DA models (first column) with corresponding coefficients $a_n$ (second column) used in the calculation of the pion-photon transition form factor by means of LCSRs. The last two columns show the values of $\chi^2_{\text{ndf}} \equiv \chi^2/\text{ndf}$ (with ndf = number of degrees of freedom) for the data in the CLEO regime and for the whole set of the data, respectively.

| BMS DA model | $(a_2, a_4, \ldots)_{\mu^2=\mu_\pi^2}$ | $\chi^2_{\text{ndf}}$ (1–9 GeV$^2$) | $\chi^2_{\text{ndf}}$ (1–40 GeV$^2$) |
|--------------|---------------------------------|---------------------------------|---------------------------------|
| BMS DA (ypsum) | (0.141, −0.089) | 0.5 | 3.1 |
| Asy DA (red triangle) | (0, 0) | 4.7 | 7.9 |
| CZ DA (blue square) | (0.394, 0) | 32.3 | 25.5 |
| Model I | (0.084, 0.137, 0.088, 0.063, 0.048, 0.039) | 2.8 | 2.4 |
| Model III | (0.104, 0.123, 0.039) | 3.2 | 2.8 |

Then, we combine the mapped 1σ error ellipse (area enclosed by a solid blue line) in Fig. 3 for the data sets in the CLEO regime (cf. Fig. 2 with the constraints from [39] and [40] (Table XII there), the aim being to extract that range of values of $(ξ^2)_π$ where they overlap. The corresponding results at the typical lattice scale $\mu_\text{lat}^2 = 4$ GeV$^2$ are, respectively, (i) $(ξ^2)_π \in [0.23 \pm 0.29]$ and $(ξ^4)_π \in [0.102 \pm 0.122]$, (ii) $(ξ^2)_π \in [0.26 \pm 0.29]$ and $(ξ^4)_π \in [0.11 \pm 0.122]$. These windows were extracted by employing a $Q^2$-dependent Borel parameter, as before in this analysis. Using instead $M^2 = 1.5$ GeV$^2$, as in [39], one would obtain only a small intersection of the corresponding region, shown in Fig. 3 by the dashed (red) line, with the lattice constraints of [39], amounting to the value $(ξ^4)_π \simeq 0.1$, while there would be no intersection at all with the lattice estimates of [40]. The sensitivity of $(ξ^2)_π$ on the choice of the Borel parameter $M^2$ provides a handle to consider the existing lattice computations [39, 40] as providing independent evidence in support of the original prescription for the Borel parameter in the LCSRs for the pion-photon transition form factor [8, 11].

V. SUMMARY AND CONCLUSIONS

In summary, three different sets of experimental data on the pion-photon transition form factor have been analyzed with the help of QCD LCSRs along the lines of our earlier works in [13, 14] and adopting the reasoning expressed in [8, 11]. The following key ingredients have been taken into account: (i) the NLO radiative correction, (ii) the twist-four contribution, and (iii) the NNLO$_{a_0}$ QCD correction [23, 24] together with the recently computed [2] twist-six contribution, these two by means of theoretical uncertainties. This is possible in our approach because in the range of the Borel parameter adopted, $M^2 < 1.0$ GeV$^2$, these two corrections, though with opposite signs, have almost the same absolute (not large) magnitude. Carrying out the analysis, evidence has been obtained that the data from CELLO [3], CLEO [4], and BaBar [5] between 1 and 9 GeV$^2$ favor a pion distribution amplitude with endpoint suppression, like the BMS model [17] (see the left panels of Fig. 2 and Fig. 3). The key for the overlap between the error ellipses of the data in the $(a_2, a_4)$ plane with the allowed region from NLC SRs is a negative value of the Gegenbauer coefficient $|a_4| \lesssim a_2$. Beyond 10 GeV$^2$, the best fit to the BaBar data on $F^{\gamma\gamma\rightarrow\pi^0}(Q^2)$ requires a sizeable coefficient $a_6$ comparable with the lower coefficients (cf. right panel of Fig. 2).

The comparison of our theoretical predictions for the scaled form factor $Q^2 F^{\gamma\gamma\rightarrow\pi^0}(Q^2)$ in Fig. 4 makes it apparent that there is an antithetic trend between the BaBar data on the pion-gamma transition form factor $f_2^\pi$ and those extracted from the the $\gamma^* \gamma \rightarrow \eta(\gamma')$ transition form factors [23]. While the latter agree very well with the BMS predictions (solid line in Fig. 4 and shaded strip in Fig. 1), the high-$Q^2$ tail of the $\pi^0$ BaBar data requires a pion DA with sizeable (or even growing with $n$) higher Gegenbauer coefficients $a_n$, or alternative theoretical schemes outside the standard QCD factorization approach, see, e.g., [26, 27, 30, 45, 46]. Similar conclusions were also drawn in [47] using Dyson–Schwinger equations.

This intriguing behavior of the BaBar data cannot be reconciled with QCD factorization in combination with LCSRs, despite the opposite claims expressed in [5]. As one sees from Fig. 4 this is not possible for our choice of the Borel window $M^2 \approx 0.7 – 0.9$ GeV$^2$, giving rise to the shaded strip, but also not for the higher values $M^2 \approx 1.5 \pm 0.5$ GeV$^2$ employed in [3] (single solid lines in the same figure). Even a large positive coefficient $a_4$ and a sizeable value of $a_6$ cannot provide sufficient reinforcement of the $\gamma^* \gamma \rightarrow \pi^0$ form factor to bridge the gap to the high-$Q^2$ BaBar data and reproduce their increase with $Q^2$ without the loss of the statistical accuracy. Quantitatively, this means that involving in the 3D data analysis the high-$Q^2$ tail of the BaBar data, makes the description inevitably worse ($\chi^2_{\text{ndf}} \gtrsim 1$) in comparison with the analysis applicable to the CLEO regime ($\chi^2_{\text{ndf}} = 0.4$). Remarkably, also the recent light-front holographic analysis in Ref. [34] yields predictions which are incompatible with the strong rise of the BaBar data at high $Q^2$, while being in agreement with those extracted from the $\gamma^* \gamma \rightarrow \eta(\gamma')$ transition form factors and rather close to our results in this region.

Bottom line: New measurements, e.g., by the Belle Collaboration, may help resolving the controversies...
around the BaBar data and understanding the dichotomy between the pion and the state $|n\rangle$ which indicates a strong violation of flavor symmetry. In addition, a precise lattice estimate of $\langle \xi^4 \rangle$ could be instrumental in fixing the sign of the Gegenbauer coefficient $a_4$ of the pion DA. Moreover, our detailed predictions in Table I in conjunction with Fig. 4 may serve as a sort of 'reference model' for various purposes: theoretical and experimental.

Acknowledgments

We would like to thank Anatoly Efremov, Simon Eidelman, Andrei Kataev, and Dmitri Naumov for stimulating discussions and useful remarks. A.B., S.M., and A.P. are thankful to Prof. Evgeny Epelebaum and Prof. Maxim Polyakov for the warm hospitality at Bochum University, where the major part of this investigation was carried out. A.B., S.M., and A.P. acknowledge financial support from Nikolay Rybakov. A.P. also wishes to thank the Ministry of Education and Science of the Russian Federation ("Development of Scientific Potential in Higher Schools" projects No. 2.2.1.1/12360 and No. 2.1.1/10683). This work was supported in part by the Heisenberg–Landau Program under Grant 2011, the DAAD (A.P.), the Russian Foundation for Fundamental Research (Grant No. 09-02-01149), and the BRFBR–JINR Cooperation Program under contract No. F10D-002.
