The synergetic effect of dual co-catalysts on the photocatalytic activity of square-like WO₃ with different exposed facets

Huihua Gong, Yue Cao, Yifeng Zhang, Yu Zhang, Kewei Liu, Hongmei Cao and Hongjian Yan

Here we report the controlled selective deposition of Pt and PbOₓ dual-cocatalysts on the edged (200) and (020) facets and the main (002) facets of square-like WO₃ nanoplates, respectively. The remarkably enhanced photocatalytic activities were observed for such assembled photocatalysts in photocatalytic water oxidation. The superior performance can be attributed to not only the light-induced preferential flow of photogenerated electrons and holes onto different facets of the square-like WO₃, thus leading to the reduction and oxidation reactions taking place on the corresponding edged and major top facets, but also the selective deposition of suitable oxidation and reduction cocatalysts onto the needed facets of square-like WO₃ to reduce the charge recombination and catalyze the redox reactions. These findings will be promising and intriguing for designing high efficiency WO₃ system for visible light water splitting.

1. Introduction

Sustainable solar energy for the clean chemical energy (renewable energy sources) from H₂ and O₂ conversion using photocatalytic water splitting under visible light is one of the promising approaches to address the environmental issues and global energy shortage crisis.¹⁻³ Tungsten oxide (WO₃), an exceptionally important n-type visible-light semiconductor material with a narrow band gap of 2.4–2.8 eV, has attracted much attention in the field of photocatalysis due to its excellent electron transport properties and good resilience to photocorrosion effects in aqueous solution.⁴⁻⁷ However, pure WO₃ is not an efficient photocatalyst due to the rapid recombination of photogenerated charge carriers and narrow photo-absorption range.⁵⁻⁷ Cocatalysts play a significant role because they can serve as the active sites for the water splitting process and trap the photoexcited electrons and holes to improve the charge-separation.⁹⁻¹⁵ It has been reported that selective deposition of suitable dual-cocatalysts (oxidation cocatalysts and reduction cocatalysts) on corresponding sites of semiconductor-based crystals (e.g., BiVO₄, TiO₂, SrTiO₃, PbTiO₃) resulted in a remarkable enhanced photocatalytic performance due to the spatial separation of the photogenerated charges between different facets and the synergetic effect of dual-cocatalysts deposited onto the needed facets.¹³,¹⁶⁻²²

Our recent research works revealed that the square-like WO₃ nanoplates with Pt loaded mainly on dominant facets shows higher photocatalytic activity than that with Pt loaded on the edged facets due to light-induced charge separation between different facets of square-like WO₃.²³ However, the activity difference is not very big owe to that platinum particles were not effective oxidation reaction promoters for promoting O₂ evolution on the dominant (002) facets of square-like WO₃. Therefore, the selective deposition of suitable cocatalysts on the needed facets of square-like WO₃, particularly loading suitable oxygen-generation promoters on the dominant (002) facets to stress the surface recombinant of charge carriers and thus improve photocatalytic performance is feasible and urgent based on the charge separation between different facets.

In this work, we have successfully prepared Pt/PbOₓ/WO₃ by using a two-step photodeposition method. PbOₓ nanoparticles as water oxidation cocatalyst were selectively deposited on the dominant (002) facets of square-like WO₃, while Pt as reduction cocatalyst were preferentially deposited on the minor (020) and (200) facets of square-like WO₃. The prepared Pt/PbOₓ/WO₃ photocatalyst exhibits a significantly increased photocatalytic O₂ evolution rate in the presence of Ag⁺ as sacrifice agent, exceeding that of WO₃ deposited with single PbOₓ or Pt cocatalyst. The superior performance can be attributed to the intrinsic nature of charge separation between the different facets of WO₃, together with the co-loading of both Pt and PbOₓ on reduction facets and oxidation facets of WO₃ to capture photogenerated electrons and holes and then reduce the charge recombination.

2. Experimental

2.1 Preparation of catalysts

2.1.1 Fabrication of square-like WO₃ nanoplates. All chemical reagents were of analytical grade and were used
without further purification. The square-like WO₃ nanoplates were synthesized by hydrothermal synthesis method as follows: 1.0 g of Na₂WO₃·2H₂O was dissolved in 20 mL deionized water under constant stirring. Then, hydrochloric acid solution (5–6 mL, HCl : H₂O = 1 : 1 v/v) was added into the solution drop by drop and magnetically stirred for 30 minutes. The obtained yellow precipitate was washed thoroughly with distilled water for removing Cl⁻, and then transferred into a 30 mL of Teflon-lined stainless steel autoclave for hydrothermal treatment at 180 °C for 24 h. As a result, the yellow precipitates were collected by centrifugation and washed with deionized water for several times and dried at 60 °C for overnight.

2.1.2 The deposition of Pt and metal oxide nanoparticles (MnOₓ, RuO₂, CoOₓ, and PbO₂) on WO₃ powder. Pt and metal oxide (MnOₓ, CoOₓ, and PbO₂) nanoparticles except RuO₂ were deposited on the WO₃ samples by photodeposition. For Pt/WO₃ preparation, the Pt cocatalysts were loaded onto WO₃ by photoreduction method in which 0.500 g of WO₃ powder was suspended in 200 mL aqueous methanol (10% in volume) containing defined amounts of H₂PtCl₆·6H₂O. The resulting suspension was then stirred and illuminated for 0.5 h with a Xe lamp after removing the dissolved oxygen completely. The suspension was collected, washed with deionized water and ethanol for several times, and finally dried at 60 °C for overnight.

The photodeposition of the PbO₂ was achieved with Pb(NO₃)₂ as the precursor. For PbO₂/WO₃ preparation, 0.500 g of WO₃ powder and appropriate amount of Pb(NO₃)₂ were suspended in 200 mL H₂O solution with different pH values by the addition of nitric acid. After photoirradiation for 1 h, the resulting suspension was centrifuged, washed with deionized water and ethanol for several times, and finally dried at 60 °C for overnight. Pt/PbO₂/WO₃ was prepared using the similar method by loading PbO₂ nanoparticles on the as-prepared platinized WO₃ powder (Pt/WO₃).

The photo-deposition of MnO₂ or CoO₃ was achieved with MnSO₄ or Co(NO₃)₂₃ as the precursor, and NaIO₃ was employed as the electron acceptor. Briefly, 0.500 g of WO₃ powder was suspended in 200 mL 0.01 M NaIO₃ aqueous solution containing a certain amount of MnSO₄ or Co(NO₃)₂₃. Then the mixture was illuminated with a Xe lamp for an hour under stirring after removing the dissolved oxygen completely. The product was collected, washed with deionized water and ethanol for several times, and finally dried at 60 °C for overnight.

RuO₂ was loaded by an impregnation method by using Ru₃(CO)₁₂ as the precursor according to the method presented previously. Typically, WO₃ powder was immersed in a tetrahydrofuran (THF) solution containing appropriate amount of dissolved Ru₃(CO)₁₂ and stirred at 333 K for 6 h for 4–5 h. The samples were finally evaporated to dryness and calcined in air at 623 K for 5 h to convert the Ru species to RuO₂. The amount of RuO₂ loaded was 0.1 wt%.

2.2 Photocatalytic reactions

The photocatalytic water splitting O₂ evolution reactions were performed in a top-irradiation reactor vessel connected to a glass closed gas circulation system. The evolved gases were analyzed by an online gas chromatograph equipped with a thermal conductivity detector (SPSIC, GC-112AT, argon carrier). Typically, 0.300 g of the as-prepared photocatalyst was dispersed in 200 mL of 0.01 M aqueous AgNO₃ solution (AgNO₃ acts as the sacrificial reagent). Before irradiated by a 300 W Xe lamp without cutoff filter, the reaction mixture was evacuated for 1 h to completely remove air and establish the adsorption-desorption equilibrium between the solution and photocatalyst with a constant magnetic stirring. The temperature of the reaction solution was maintained at 283 K by a flow of cooling water during the reaction. The gas generated was analyzed every 1 h.

2.3 Characterization

Scanning electron microscope (SEM) images of the samples was performed with JSM-5900LV Scanning Electron Microscopy (SEM, JEOL, Japan). Transmission electron microscopy images (TEM), high-resolution (HR) TEM images of the samples were obtained on transmission electron microscope (TEM; Tecnai G2 F20 S-TWIN). Powder X-ray diffraction (XRD) patterns were obtained using a X-Pert Pro diffractometer with Cu Kα radiation (λ = 1.5406 Å) at a scanning speed of 4° min⁻¹. The UV-vis diffuse reflectance absorption spectra (DRS) were recorded on a UV-vis spectrophotometer (UV3600, Shimadzu) by using BaSO₄ as a reference. The photoluminescence (PL) spectra of the samples was carried out with a Hitachi F-7000 photoluminescence spectrophotometer (Hitachi F-7000) and the excitation wavelength was 230 nm. X-ray photoelectron spectroscopy (XPS) spectra were measured on a V4105 instrument (Thermo Electron, USA) with a Mn Kα radiation source.

3. Result and discussion

Fig. 1 shows the SEM image of square-like WO₃ nanoplates was synthesized by hydrothermal method. The size of the WO₃ nanoplates was between several hundred nanometres and micrometres in length with a thickness of approximately 15–20 nm. The rectangular square-like WO₃ nanoplate with predominant facets of (002) and side facets of (020) and (200) based on our recent works. It is known that Pt was used as the
powerful reduction cocatalysts for high activity WO₃. The choice of suitable oxidation cocatalysts is another important factor for photocatalytic water oxidation reaction. Fig. 2 shows the photocatalytic water oxidation activities of WO₃ loaded with different oxidation cocatalysts when platinum is used as the reduction cocatalyst. Four metal oxides, MnO₂, RuO₂, CoOₓ, and PbOₓ, known as water oxidation cocatalysts, can catalyze the water oxidation reactions to enhance the photocatalytic oxygen evolution of WO₃. ¹⁷–¹⁸ MnO₂, CoOₓ, PbOₓ, and Pt were deposited by photo-deposition method except that RuO₂ was deposited by the impregnation method. The photocatalytic O₂ evolution rate over WO₃ loaded with MnO₂, RuO₂, CoOₓ or PbOₓ is 446.8, 490.6, 636.7, 929.7 µmol h⁻¹ g⁻¹, respectively. The activity order is MnO₂ < RuO₂ < CoOₓ < PbOₓ. Compared to O₂ evolution rate of Pt/WO₃ (479.1 µmol h⁻¹ g⁻¹), the photocatalytic activity of Pt–MnO₂/WO₃ was lower than Pt/WO₃, indicating that the MnO₂ have less contribution to the O₂ evolution of WO₃. Almost very little improvement of photocatalytic activity was observed when RuO₂ was deposited. CoOₓ show more effect on the enhanced photocatalytic activity than RuO₂. The water oxidation activity was increased much more obvious when PbOₓ is used as the oxidation cocatalyst, suggesting that the loading of PbOₓ and Pt as cocatalysts together shows a synergistic effect in photocatalysis.

The band edge position for WO₃ and some metal oxides are shown in Fig. 3. The electronic structures of PbO and PbOₓ have been relatively well understood, while the band structure and the nature of metallic behaviour of PbOₓ are still controversial in recent years.²⁹ Therefore the band gap of PbOₓ is not listed in Fig. 3. The photogenerated holes in the valence band (VB) of WO₃ can be transfer to metal oxides, since the VB potential of WO₃ is more positive than that of metal oxides. The different activities of MOₓ/Pt/WO₃ (M = Co, Ru, Pb, Mn) may be ascribed to the different matching degrees of energy band level and electronic structures between WO₃ and metal oxides.²²,²³,³¹,³⁴ It is known that the cocatalyst and semiconductor should have compatible lattice and electronic structures with suitable Fermi levels or band levels, thus the migration of photogenerated carriers can be promoted by the internal field at the interface.²²,²³,³¹ Furthermore, the processing condition and method of preparation metal oxides catalyst also play major roles in the stability, crystallinity, and the size of metal oxides particles, which are greatly affect the activities of catalysts.³² Possible differences in roughness factors also can contribute to difference in performance of as-prepared samples. For example, stability for RuO₂, the size of CoOₓ particles affects photocatalytic activity of photocatalyst.³³,³⁴

Photo-oxidation deposition of PbOₓ on WO₃ was prepared by using Pb(NO₃)₂ as the precursor in solution with different acidity. Fig. 4 shows the effect of the different acidity condition of loading PbOₓ on photocatalytic activity over Pt/PbOₓ/WO₃. The pH values were 1.8, 2.4, 3.77, 4.8, and 7 in the order from small to large. It clearly shows that the highest activity of Pt/ PbOₓ/WO₃ was observed at approximately pH in the range of 2 to 4. In order to clarify the influence of acidity on the photocatalytic activity, PbOₓ/WO₃ (0.5 wt%, Pb) samples prepared by photooxidative deposition of PbOₓ at three different pH values of 1.8, 2.4 and 4.8 were selected to characterize by X-ray photoelectron spectroscopy (XPS). The survey XPS spectrum (Fig. 5a) shows that the main elements on the surface of the composite were W, O, Pb and C. The C 1s peak observed in the survey scan is due to the carbon contamination which was used to calibrate the binding energy. For PbOₓ/WO₃ samples prepared at pH values of 1.8 and 2.4, the peaks locates at around
35.50 and 37.61 eV (see Fig. 5b), related to W 4f_{7/2} and W 4f_{5/2} binding energies of W(v) oxidation state in the tungsten oxide sample.\textsuperscript{8,26} The O 1s peak (Fig. 5c) at 530.30 eV is associated with the lattice oxygen in WO\textsubscript{x}, and the other peak at 531.97 eV corresponds with surface adsorbed hydroxide and water.\textsuperscript{8,26,42,43}

The Pb 4f spectrum for PbO\textsubscript{x}/WO\textsubscript{3} sample prepared at pH value of 2.4 exhibited two binding energies at 138.80 and 143.64 eV, corresponding to Pb 4f_{7/2} and Pb 4f_{5/2} for Pb\textsuperscript{2+}, respectively. This result indicated that PbO\textsubscript{2} was formed when the PbO\textsubscript{x} was loaded at pH value of 2.4.\textsuperscript{30,42,46} For PbO\textsubscript{2}/WO\textsubscript{3} sample prepared at pH values of 4.8 (near neutral pH), the Pb 4f spectrum exhibited two peaks at 138.95 and 143.85 eV, corresponding to Pb 4f_{7/2} and Pb 4f_{5/2} in the form of Pb\textsubscript{4+},\textsuperscript{42,47,48} respectively, which indicated both states of Pb(II) and Pb(IV) exist in this photocatalyst. With the increase in acidity, nitric acid will gradually dissolve lead oxide to produce Pb\textsuperscript{2+}, then the Pb\textsuperscript{2+} was oxidized by photo-generated holes (Pb\textsuperscript{2+} + 2H\textsubscript{2}O + 2h\textsuperscript{+} = PbO\textsubscript{2} + 4H\textsuperscript{+}). The increased peak intensity of Pb observed in the XPS of sample with pH value of 2.4 suggests that solution pH not only affect the chemical states of Pb in PbO\textsubscript{x} but also affect the loading amount of PbO\textsubscript{2}. Therefore, the different photocatalytic performances (as shown in Fig. 4) of Pt/PbO\textsubscript{x}/WO\textsubscript{3} prepared by pH values of 2.4 and 1.8 may be caused by the loading amount of PbO\textsubscript{2}, and the different performances of Pt/ PbO\textsubscript{x}/WO\textsubscript{3} prepared at pH = 2.4 to 7 may be caused by the slow change of valence states of lead in loaded oxides of lead. Compared to the samples prepared at pH values of 2.4 and 1.8, the W 4f and O 1s peaks of PbO\textsubscript{x}/WO\textsubscript{3} sample prepared at near neutral pH (pH 4.8) show a small shift about 0.2 eV toward high binding energy, which could be due to the effect of states in the loaded PbO\textsubscript{2}.

The XRD patterns of the prepared catalysts are shown in Fig. 6. The patterns clearly demonstrated that the pure WO\textsubscript{3} exhibits a monoclinic phase structure with obvious characteristic diffraction peaks at 2θ values of 23.15, 23.61, 24.37, 33.30, and 34.19°, corresponding to the (002), (200), (200), (022) and (202) planes, respectively (JCPDS no. 72-1465, a = 7.300 Å, b = 7.530 Å, and c = 7.680 Å). All samples have monoclinic WO\textsubscript{3} structure and the cocatalysts loading does not influence the crystal structures of WO\textsubscript{3}. In the XRD patterns of Pt/ WO\textsubscript{3} and Pt/PbO\textsubscript{x}/WO\textsubscript{3} samples, no related peaks of Pt or PbO\textsubscript{x} except for monoclinic WO\textsubscript{3} are observed because of the tiny amount of Pt(0.5 wt%), PbO\textsubscript{x}(0.1 wt%), small size and high dispersion in the samples.

The morphology of square-like WO\textsubscript{3} deposited with Pt cocatalyst (0.5 wt%) was observed, and the SEM and TEM image was shown in Fig. 7a and b, respectively. Obviously, Pt nanoparticles with a primary size of 2–3 nm were mainly deposited on the side (020) and (200) facets of the square-like WO\textsubscript{3} nanoparticles and seriously aggregated. The phenomenon of preferred deposition of Pt is due to intrinsic differences in surface charge of square-like WO\textsubscript{3} nanoparticles leading sorption-induced deposition of Pt on square-like WO\textsubscript{3}.\textsuperscript{49} Prior to photo-reduction, since the edges appear positively charged and then preferentially adsorb the negatively charged [PtCl\textsubscript{6}]\textsuperscript{2–} ions, thus leading to the observed sorption-determined preferred deposition of platinum on the edged facets of square-like WO\textsubscript{3}.\textsuperscript{49} Fig. 7c shows the SEM image of WO\textsubscript{3} deposited with PbO\textsubscript{x} (Pb, 0.1 wt%) by photo-oxidation deposition method. As shown in Fig. 7c, PbO\textsubscript{x} with size of more than 5 nm were mainly loaded on the dominant (002) facets of square-like WO\textsubscript{3}, while almost no PbO\textsubscript{x} particles were observed on the side (020) and (200) facets.

The TEM and SEM images of the square-like WO\textsubscript{3} deposited with Pt and PbO\textsubscript{x} dual cocatalysts by \textit{in situ} photo-reduction and photo-oxidation deposition methods were also obtained and are shown in Fig. 8. The HRTEM image (Fig. 8d) shows that the lattice fringes of nanoparticles on side (020) and (200) facets is 0.227 nm, which can be indexed to the (111) plane of Pt (JCPDS, no. 70-2431), and it is also hard to find out the PbO\textsubscript{x} on the side (020) and (200) facets of square-like WO\textsubscript{3}. As shown in Fig. 8a, it is clearly observed that the surface of tungsten trioxide including the small and dominant facets are covered with cocatalysts. PbO\textsubscript{x} and Pt can be easily discerned through the particle sizes. Combining both the TEM and SEM images shown.
in Fig. 7 and 8, we can clearly confirm that the PbO$_x$ nanoparticles with a diameter of around 5–10 nm are selectively deposited on the dominant (002) facets of square-like WO$_3$, while Pt nanoparticles with smaller particle size were deposited on the side (020) and (200) facets of square-like WO$_3$. Considering that the basal (002) planes indicates a weak negative surface charge,$^{49}$ dark sorption of the positively charged Pb$^{2+}$ ions prior to photoreduction is probably preferred at the dominant (002) facets rather than positively charged edges. When illumination, light-induced spatial separation of the photogenerated electrons and holes toward the edged facets and the dominant crystal facets of square-like WO$_3$ nanoplates, respectively.$^{23}$ The photogenerated holes that directional migration to (002) facets will oxidize the divalent lead ions to PbO$_x$, thus resulting in preferred loading of PbO$_x$ on the dominant planes of WO$_3$.

As shown in Fig. 9, the photocatalytic oxygen evolution activity is strongly dependent on the cocatalysts photodeposited on the surface of the square-like WO$_3$. The highest water oxidation activity is achieved for the Pt/PbO$_x$/WO$_3$ sample with metallic platinum and PbO$_x$ particles selectively photodeposited on the edged and dominant facets, respectively. The rate of O$_2$ evolution on Pt/WO$_3$ and PbO$_x$/WO$_3$ is 479.1 µmol h$^{-1}$ g$^{-1}$ and 599.0 µmol h$^{-1}$ g$^{-1}$, respectively. Loading PbO$_x$ on the dominant (002) facets of WO$_3$ can enhance the photocatalytic O$_2$ evolution rate further. However, the O$_2$ evolution rate on Pt/PbO$_x$/WO$_3$ is 929.7 µmol h$^{-1}$ g$^{-1}$. The photocatalytic water oxidation activity of Pt/PbO$_x$/WO$_3$ is nearly double than that of Pt/WO$_3$, indicating that PbO$_x$ nanoparticles located on the dominant facets of square-like WO$_3$ have a positive effect on water oxidation reaction.

As demonstrated in Fig. 10, the UV-vis diffuse reflectance spectra of the square-like WO$_3$ loaded with different cocatalysts show similar absorption property to pure WO$_3$ with a strong absorption range from 200 to 350 nm, but slightly weakened the absorption intensity due to that the cocatalysts shadow the photocatalyst absorbing the light.$^{50}$ It can be deduced from the adsorption edge that all the samples has a band gap of 2.78 eV, indicating that the loaded of PbO$_x$ and Pt on the surface of square-like WO$_3$ did not change its band gap. The photoluminescence spectra (Fig. 11) of the photocatalysts give more information of the density of recombination of photogenerated electron–hole pairs. Pt/WO$_3$ and PbO$_x$/WO$_3$ exhibit weaker emission peak intensity than pure WO$_3$ and a significantly decreased PL intensity is observed for Pt/PbO$_x$/WO$_3$ in the wavelength range of 300–800 nm, suggesting that the lower electron–hole recombination rate in Pt/PbO$_x$/WO$_3$. The result of PL is in good agreement with that of photocatalytic performances (Fig. 9). Such a decreased electron–hole recombination might be ascribed to selective deposition of a suitable dual-cocatalysts onto the needed facets of square-like WO$_3$ leading accelerated transfer of the photogenerated electrons and holes from the surfaces of WO$_3$.

It has been reported that the deposition of suitable dual-cocatalysts on the needed facets of semiconductor-based
charges between facets.

attributed to the spatial separation of the photogenerated

electrons toward the dominant (002) facets and edged facets of

that light-induced preferential

\( \text{O}_2 \text{ evolution takes place on the hole-rich (002) major top facets, while the reduction reaction takes place on the electron-rich (020) and (200) facets. At the same time, PbO}_2\) cocatalysts loaded on the dominant facets act as oxidation sites for \( \text{O}_2 \) evolution to catalyze the four-electron water oxidation to

\( \text{H}_2\text{O} \rightarrow \text{O}_2 + 4\text{H}^+ + 4e^- \) with Pt loaded on the edged facets are to offer reduction sites for \( \text{Ag}^+ \) and catalyze the reduction reactions, namely the

reduction of \( \text{Ag}^+ \) to Ag. The simultaneous existence of Pt and

PbO2 cocatalysts is supposed to be synergistically working for the efficient separation and transfer of the photoexcited electrons and holes, thus contributing to the photocatalytic performance of Pt/PbO2/WO3.

4. Conclusion

In conclusion, square-like WO3 nanoplates with specific exposed crystal facets were synthesized by hydrothermal method. Pt and PbO2 dual cocatalysts were selectively deposited on the edged (200) and (020) facets and the dominant (002) facets of square-like WO3 by photo-deposited, respectively. The WO3 deposited with dual cocatalysts show remarkable enhanced photocatalytic activities than that WO3 loaded with single cocatalyst. The enhanced photocatalytic performances are due to light-induced spatial separation of the photogenerated electrons and holes toward different facets of square-like WO3 nanoplates and selectively deposition of suitable dual-cocatalysts onto the needed facets of square-like WO3.
