ABSTRACT

We present the analysis of four XMM–Newton observations of the narrow-line quasar PG 1543+489 at z = 0.400 carried out over a rest-frame time-scale of about 3 yr. The X-ray spectrum is characterized by a broad, relativistic iron Kα emission line and a steep photon index, which can be both explained by an ionized reflection model, where the source of X-ray photons is presumably very close to the black hole. If this were the case, strong light-bending effects are expected, and actually they provide the most plausible explanation for the large equivalent width (EW = 3.1 ± 0.8 keV in the source rest frame) of the iron line. Although the light-bending model provides a good description of the X-ray data of PG 1543+489, it is not possible to rule out an absorption model, where obscuring matter partially covers the X-ray source. However, the apparent lack of variations in the properties of the absorber over the time-scale probed by our observations may indicate that this model is less likely.

Key words: galaxies: active – galaxies: nuclei – quasars: general – quasars: individual: PG 1543+489.

1 INTRODUCTION

The Palomar–Green (PG) quasars (Schmidt & Green 1983) represent one of the best studied samples of active galactic nuclei (AGN). Because of their relatively high X-ray luminosities, over the last decade their properties have been widely investigated by almost all the X-ray satellites, from ROSAT (e.g. Laor et al. 1997) to ASCA (e.g. George et al. 2000), BeppoSAX (e.g. Mineo et al. 2000) and, lastly, XMM–Newton (Porquet et al. 2004; Jiménez-Bailón et al. 2005; Piconcelli et al. 2005; Brocksopp et al. 2006). In particular, the high-energy throughput of the XMM–Newton EPIC instruments have recently allowed a detailed investigation of their spectral properties in the ≲0.3–10 keV band (e.g. Jiménez-Bailón et al. 2005; Piconcelli et al. 2005), showing the ubiquitous presence of soft excesses and iron Kα emission lines, as well as, in half of the sample, of warm absorbers.

Here we present the X-ray analysis of the XMM–Newton spectrum of PG 1543+489, a narrow-line quasar (NLQ) [the full width at half-maximum (FWHM) of the Hβ line is 1630 km s−1 (Aoki, Kawaguchi & Ohta 2005)] at a redshift of z = 0.400. According to optical and ultraviolet mass scaling, this quasar is likely characterized by a (1–2.4) × 108 M☉ black hole (D’Elia, Padovani & Landt 2003; Vestergaard & Peterson 2006); a even larger black hole mass was estimated by Brocksopp et al. (2006) using a spectral energy distribution (SED) fitting approach. Furthermore, from the measured λL5100Å (∼ 1045.6 erg s−1; Aoki et al. 2005) and adopting the bolometric correction for broad-line (Type 1) quasars reported in Richards et al. (2006), we can estimate a remarkably high Eddington ratio [defined as $L_{\text{bol}}/L_{\text{Edd}}$, where $L_{\text{bol}}$ is the bolometric luminosity and $L_{\text{Edd}} = (1.3–3.1) × 10^{46}$ erg s−1 is the Eddington luminosity] of ≲1.3–3.7 for PG 1543+489 (versus 2.3 for Baskin & Laor 2005). This value, similar to that obtained by Aoki et al. (2005), appears significantly higher than the one estimated from the observed 2–10 keV luminosity (∼ 1.1 × 1044 erg s−1; see Section 2.4) using the Elvis et al. (1994) average SED of broad-line quasars, which is ≲0.1–0.3. The difference in the estimates of the bolometric luminosity (from the λL5100Å and the 2–10 keV luminosity) can be partially overcome by assuming Equation 21 in Marconi et al. (2004; see their section 3.2). In this case, the bolometric luminosity derived using the B-band luminosity is a factor of ≈4.8 lower than the one obtained by Richards et al. (2006) from the $\lambda L_{5100Å}$. We expect that in objects with large Eddington ratios the metallicity is
considerably high (e.g. Shemmer et al. 2004; Netzer & Trakhtenbrot 2007), as actually observed in PG 1543+489 (Aoki et al. 2005).

A peculiarity of PG 1543+489 is the bluishness of the [O III] 5007 Å line (1150 km s⁻¹ with respect to the systemic velocity of the galaxy) and the blue asymmetry of its profile (Aoki et al. 2005). The large [O III] bluishness of the so-called 'blue outliers' ¹ (to which PG 1543+489 belongs) has been theoretically interpreted as the result of an outflow whose receding part is obscured by an optically thick accretion disc (Zamanov et al. 2002) or by a scenario in which the narrow-line region clouds are entrained in a decelerating wind, possibly linked to the high Eddington ratio typical of the 'blue outliers' (Komossa et al. 2008). The amount of bluishness does not appear to correlate with the Eddington ratio; however, there is a clear connection between being a 'blue outlier' and the Eddington ratio itself (Aoki et al. 2005); this issue clearly needs further and extended investigations. Interestingly, PG 1543+489 has the largest [O III] bluishness (relative to Hβ) among the 280 broad-line AGN in the sample of Marziani et al. (2003a); although outflow phenomena have been reported in other narrow-line Seyfert 1 galaxies (NLS1s) and NLQs, to our knowledge PG 1543+489 shows the most extreme value of bluishness among AGN not classified as broad absorption-line (BAL) quasars. The remarkably strong asymmetric profile of the bluishshifted C IV emission line (Baskin & Laor 2005) provides a further indication that PG 1543+489 is an intriguing source with a large Eddington ratio.

Previous observations in the soft and hard X-rays have shown that NLS1s and NLQs have typically steeper X-ray spectra [in both the soft (e.g.oller, Brandt & Fink 1996) and hard X-ray band (e.g. Brandt, Mathur & Elvis 1997)] than 'normal' broad-line quasars, whose photon index is Γ = 1.9–2.0 in the 2–10 keV band (e.g. Reeves & Turner 2000; Page et al. 2003) and independent on the source redshift and luminosity (e.g. Picconcelli et al. 2003; Page et al. 2005; Shemmer et al. 2005; Vignali et al. 2005); but see also Dai et al. 2004 and Saez et al. 2008 for different results). In Type 1 AGN, a well-established anticorrelation between the photon index and the Hβ FWHM exists both in the soft and hard X-ray band (e.g. Laor et al. 1994; Brandt et al. 1997; Laor et al. 1997). Based on the reasoning that eventually led to the Kaspi et al. (2000) results, the FWHM of the Hβ line was suggested to be an accretion rate indicator in broad-line AGN (e.g. Boroson & Green 1992; Brandt & Boller 1998), i.e. objects with narrower Hβ lines are thought to accrete at a higher fraction of the Eddington limit. On the basis of this finding, Reeves & Turner (2000) explained the steepening of the X-ray spectrum as due to a larger Compton cooling of the hard X-ray emitting corona (e.g. Pounds, Done & Osborne 1995; see also Puchnarewicz et al. 1995).

In this context, the X-ray observations of PG 1543+489 are meant to provide a powerful insight on the emission in the innermost regions of the quasar; the presence of a steep photon index, as indicated by the ASCA observation (George et al. 2000), coupled with the narrow Hβ emission line, would imply a high accretion rate for this source (see the recent works by Shemmer et al. 2006; Shemmer et al. 2008 and references therein), likely related to the outflow phenomena.

Hereafter we adopt H⊙ = 70 km s⁻¹ Mpc⁻¹ in a Λ cosmology with ΩM = 0.3 and ΩΛ = 0.7 (Spergel et al. 2003).

2 XMM–Newton OBSERVATIONS OF PG 1543+489

The XMM–Newton data reported in this paper consist of four observations, the first of which (dated 2003 February) being retrieved from the archive and published by Matsumoto, Leighly & Kawaguchi (2006) and Brocksopp et al. (2006). The remaining three observations were obtained in XMM–Newton AO6 call for proposals, and the source was observed in 2007 June. The observation log of all the XMM–Newton observations of PG 1543+489 is reported in Table 1.

2.1 EPIC data reduction

The XMM–Newton data were processed using standard sas v7.0.0 (Gabriel et al. 2004) and FTOOLS tasks. The event files were filtered to include events with pattern ≤4 and ≤2 for the pn and MOS instruments, respectively, over the energy range 0.3–10 keV. High background intervals are present in all of the observations; the procedure to obtain a good compromise between clean event files and relatively good statistics consists of using the script xmmlight_clean.csh ² which performs a recursive 3σ cleaning on the light curves in the 10–15 keV energy range (binned in 100-s intervals) until the mean count rate per bin is constant. The goodness of this cleaning process (proven to be effective in past observations) has been checked on the resulting light curves and images, adopting different bin intervals, and by comparison with other cleaning methods (e.g. adopting the procedure reported in Baldi et al. 2002), confirming the achievement of a relatively good final result. The only exception is the last observation carried out in 2007 (OBS_ID = 0505050301), which still shows the presence of significant residual flares after the cleaning process, hampering a good analysis of the data. For this reason, the data of this observation will not be considered further. The final ‘cleaned’ exposure times are reported in Table 1.

To extract X-ray spectra, we used variable source-extraction aperture radii to maximize the signal-to-noise ratio (S/N) over the entire 0.3–10 keV energy range and obtain good counting statistics for moderate-quality spectral analysis. Radii vary from 27 to 45 arcsec for the pn, and from 24 to 30 arcsec for the two MOS cameras. The background was taken from circular regions, in the same chip (to avoid significant spatial variations across the detector) and close to PG 1543+489 (without being contaminated by the target itself) with radii of 90 arcsec. The adoption of multiple background regions did not provide significantly different results. The redistribution matrix files (RMFs, which include information on the detector gain and energy resolution), and the ancillary response files (ARFs, which include information on the effective area of the instrument, filter transmission and any additional energy-dependent efficiencies) were created with the SAS tasks rmfgen and arfgen, respectively. The resulting pn (MOS) spectra were grouped with a minimum of 20 (15) counts per bin using the task grpaha, in order to apply the χ² statistic, and fitted with xspec v12.4.0 (Arnaud 1996).

During each observation, the flux level in the soft (0.5–2 keV) and hard band (2–10 keV) did not show significant (i.e. above the ≈20 per cent) variations, according to a χ² test.

2.2 Optical monitor data

In order to obtain information on the broad-band (UV-to-X-ray) spectral properties of PG 1543+489 (see Section 3), we used the

¹ According to the definition of Marziani et al. 2003b, a ‘blue outlier’ is a source where Δvβ([O III]) = vβ([O III])<0.7–300 km s⁻¹, where vβ is the radial velocity as measured on the Fe ii subtracted spectrum.

optical monitor (OM) products, which consist of flux densities and magnitudes in selected filters. While for the archival observation only data taken with the UVM2 filter (having an effective wavelength of 3440 Å), and in the first observation of 2007 June (OBS ID = 0505050201) also the UVM2 filter was operating.

2.3 X-ray spectral analysis

At first, we checked the pn, MOS1 and MOS2 data for consistency (over the ≈0.3–10 keV band) within each observation, assuming a power-law model, and found generally a good agreement in both the photon index and the overall shape of the residuals among the different EPIC instruments. Some residuals appear evident in the ≈3–6 keV energy range, being particularly prominent in the pn data (likely because of its higher effective area compared to that of the MOS cameras). As an example, in Fig. 1 (left-hand panel) we report the fitting to the pn data with a power-law model and Galactic absorption using the archival data only, since this observation has subsequently driven the science case of the proposed and awarded 2007 observations. The residuals resemble those expected in case of a broad, relativistic (because of the pronounced red wing) iron line, as suggested by the close-up of the deviations centred in the presumably broad iron feature shown in Fig. 1 (right-hand panel).

Given the necessity of a proper investigation of the hard-band spectral complexities of PG 1543+489, we decided to re-extract the source spectra from all EPIC instruments adopting an ‘optimized’ radius for each source extraction region (see Table 2). This radius was chosen to maximize the S/N over the 2–10 keV band using the task eregionanalyse within the SAS. The results from this task were checked against different choices of the background regions. The spectra were binned with a minimum of 20 counts per bin in all pn observations and 15 counts per bin in all MOS data. Good source signal is present in the ≈0.3–7 keV band, then at higher energies the background starts providing a relevant contribution in the spectral fitting. For this reason, to provide robust spectral results, the analyses presented in the following are produced in this energy range, at the expense of a total of ≈150 counts with respect to the number of counts in the 0.3–10 keV band.

Despite the observed source flux variations over the rest-frame time-scale of ≈3 yr probed by our observations (the 0.5–10 keV flux was ≈5 × 10$^{-11}$ erg cm$^{-2}$ s$^{-1}$ in 2003 and increased by

![Figure 1](https://example.com/figure1.png)

**Figure 1.** Left-hand panel: Fitting to the archival pn data (OBS ID = 0153220401) over the ≈0.3–10 keV energy range using a power-law model and Galactic absorption. The data-to-model ratios are shown in the bottom panel in units of $\sigma$. Right-hand panel: Close-up of the deviations (in units of $\sigma$) in the ≈1.5–7 keV band of the observed EPIC pn data adopting a power-law model fitted to the (0.3–3 keV) + (6–10 keV) range and extrapolated to the whole energy interval.
all spectral fits include absorption due to the line-of-sight Galactic column density of $N_H = 1.59 \times 10^{20} \text{cm}^{-2}$ (Dickey & Lockman 1990), and Anders & Grevesse (1989) abundances are assumed.

Similarly to the situation illustrated in Fig. 1, a single power-law model is not able to reproduce the data of all the EPIC data, leaving strong residuals in the hard band [see Table 3, model (a) and Fig. 3]. The inclusion of a broad line, either modelled with a Gaussian [model ZGAUSS in XSPEC; model (b) in Table 3] or a relativistic component (models DISKLINE and LAOR in the case of a black hole in the Schwarzschild and Kerr metric, respectively – models (c) and (d) in Table 3; Fabian et al. 1989; Laor 1991) improves the fit by $\Delta \chi^2 \approx 19–50$ for 2–3 additional degrees of freedom (the line energy, width and normalization in the ZGAUSS model, and line energy and normalization in the relativistic models, where the inner radius of the accretion disc was fixed to the minimum radius allowed by the two metrics and the emissivity index was left to its default value in the LAOR model). Although the highest improvement, in terms of $\chi^2$, is obtained using a Gaussian iron line, the width of this line ($\sigma = 2.98^{+1.12}_{-0.53} \text{keV}$), coupled with its centroid energy (unconstrained), suggests that a more accurate spectral parameterization (e.g. a relativistic feature) is needed to properly reproduce the data. Using the LAOR model (c), the improvement in the spectral fitting corresponds to the >99.999 % per cent (according to the F-test) with respect to the single power-law model; since the iron line normalization was allowed to be negative in the spectral fitting, the F-test can still be considered a reliable method to derive the statistical significance of the line (see Protassov et al. 2002). The best-fitting rest-frame energy, $6.7^{+0.2}_{-0.1}$ keV in the case of a LAOR line, is consistent, within the errors, with that obtained in case of a DISKLINE case, with the former model being preferred on a statistical basis (Table 3) and from visual inspection of the data-to-model ratios. The line energy is consistent with neutral iron up to Fe XXV. The equivalent width (EW) of the relativistic line ($EW = 3.1 \pm 0.8 \text{keV}$ in the source rest frame) is much larger than that measured in case of detection of broad features by ASCA and XMM–Newton for a sample of nearby AGN (EW $\approx 230–250$ eV; Nandra et al. 1997; Guainazzi, Bianchi & Dovčiak 2006); we defer a more exhaustive discussion on possible causes of this strong feature in Section 3. The rest-frame line energy versus normalization in the LAOR model, shown in Fig. 4, is likely suggestive of a more complex modelling for PG 1543+489.

The power-law photon index does not vary significantly with the inclusion of a broad feature, being $\Gamma \approx 2.7–2.8$, in agreement with

| Model | $\Gamma$ | $E$ | EW | $\xi$ | $N_H$ | Covering fraction | $\chi^2$/d.o.f. |
|-------|---------|-----|-----|------|------|------------------|----------------|
| (a)   | 2.70 $\pm$ 0.03 | | | | | | 495.5/442 |
| (b)   | 2.81 $^{+0.07}_{-0.04}$ | 4.09 unc. | 2.35 $^{+0.61}_{-1.23}$ | | | | 445.0/439 |
| (c)   | 2.75 $\pm$ 0.03 | 6.71 $^{+0.21}_{-0.55}$ | 3.09 $\pm$ 0.84 | | | | 458.9/440 |
| (d)   | 2.72 $^{+0.02}_{-0.03}$ | 6.33 $\pm$ 0.11 | 1.12 $^{+0.20}_{-0.60}$ | | | | 476.4/440 |
| (e)   | 2.32 $^{+0.01}_{-0.02}$ | | | | | | >6760 |
| (f)   | 2.78 $\pm$ 0.04 | | | | | | 460.8/441 |

The relative normalization of the MOS cameras with respect to the pn is 1.03–1.04 in all the spectral fittings presented here. (1) Reference for the model adopted in the spectral fitting (see below and Section 2.3 for details); (2) photon index over the 0.3–7 keV bandpass; (3) rest-frame energy of the line (keV); (4) rest-frame EW of the line (keV); (5) ionization parameter $\xi = 4.7N_{\text{ion}}/N_H$ (erg cm s$^{-1}$), where $F_{\text{ion}}$ is the total illuminating flux and $N_H$ is the hydrogen number density (part cm$^{-3}$) of the illuminated slab; (6) rest-frame column density (in units of $10^{22}$ cm$^{-2}$); (7) covering fraction of the absorbing matter; (8) goodness of the fit in terms of $\chi^2$/number of degrees of freedom, d.o.f.).

Adopted models: (a) power law; (b) power law and broad Gaussian iron line; (c) power law and relativistic (LAOR) iron line; (d) power law and relativistic (DISKLINE) iron line; (e) ionized reflection (REFLION model), convolved with a relativistic blurring kernel from the Laor (1991) code (KDIBLUR); (f) power law plus partial covering absorption.
that derived from ASCA data. Although warm absorbers and soft excesses are often detected in PG quasars (e.g. Reynolds 1997; Porquet et al. 2004; Piconcelli et al. 2005), we must note that there is no strong indication that the main features of warm absorbers (i.e. the O vii and O viii absorption edges and the unresolved transition array, UTA; e.g. Piconcelli et al. 2005) are present in the EPIC spectra; furthermore, the source redshift (z = 0.400) is such to plausibly move a significant fraction of any additional soft component below the energy interval where the EPIC instruments are mostly sensitive.

Given the recent claims that NLS1 and NLQ X-ray spectra could be reflection dominated (e.g. Fabian et al. 2002, but see also Done 2007) and the convincing results obtained for some AGN of this class, where the whole X-ray continuum emission and iron Kα line are well explained in terms of reflection (e.g. Fabian et al. 2004; Gallo et al. 2004a and references therein), we tried to fit all the data using a ionized reflection model (REFLION3 into XSPEC; Ross & Fabian 2005), which incorporates both line emission with Compton broadening and reflection continuum, convolved with a relativistic blurring kernel from the Laor (1991) code [KDBLUR into XSPEC; model (e) in Table 3]. This spectral parameterization is well suited to represent the light-bending model, where the presence of a reflection-dominated spectrum is interpreted as due to strong light-bending effects at work close to the black hole (Miniutti & Fabian 2004; see section 3). The iron abundance was fixed to solar, and the other spectral parameters frozen to their default values. The quality of the fit ($\chi^2$/d.o.f. = 460.8/441) is similar to that obtained in the case of a relativistic iron line plus a steep X-ray continuum, the only difference being a flatter photon index ($\Gamma = 2.3^{+0.04}_{-0.02}$) and, likely, a more physical description of the X-ray emission of PG 1543+489: the spectrum is shown in Fig. 5.

Unfortunately, the quality of the data does not allow us to constrain the ionization parameter ($\xi = 4\\pi F_{\text{tot}}/n_H > 6760$ erg cm s$^{-1}$, where $F_{\text{tot}}$ is the total illuminating flux and $n_H$ is the hydrogen number density) and to distinguish, on the basis of the $\chi^2$ and the inner radius of the accretion disc (once left free to vary), between a maximally spinning black hole and a non-spinning Schwarzschild black hole. In these highly ionized conditions, the disc acts like a perfect reflector (see Ross & Fabian 2005), whose main properties are a power law similar to the incident one, a modest Compton hump, and a ‘smeared’ iron line and edge, due to the effects of Comptonization. For this reason, it is difficult to place constraints on the relative strength of the reflection continuum with respect to the incident power law, which is broadly constrained in the range 1.5–6.0 for solar abundances. Although the optical spectrum indicates iron overabundance (see section 2.3 of Aoki et al. 2005), we note that, from an X-ray perspective, a slightly better statistical result (improvement by $\Delta \chi^2 \approx 9$ for one additional degree of freedom with respect to the model with iron abundance fixed to solar) is achieved leaving the iron abundance free to vary in the spectral fitting (and the Fe abundance relative to the solar value is 0.64$^{+0.26}_{-0.23}$).

Figure 4. 68, 90 and 99 per cent confidence contours showing the rest-frame energy versus photon flux of the relativistic iron emission-line (LAOR model in XSPEC).

Figure 3. Fitting to the pn (triangles), MOS1 (filled circles) and MOS2 (stars) spectral data of the three observations over the 0.3–7 keV energy range using a power-law model and Galactic absorption. The data-to-model ratios are shown in the bottom panels in units of $\sigma$. 

\[ \text{Counts s}^{-1} \]

\[ \text{OBS_ID 0505050201} \]

\[ \text{OBS_ID 0505050701} \]
We also note that the iron edge at $\approx 7.1$ keV or sharp drop in the continuum flux observed in some NLS1s (e.g. Boller 2004; Gallo et al. 2004b) and interpreted in terms of reflection cannot be investigated by the current data, because at these high energies the source and background signals become approximately comparable (see Section 2.3).

Finally, we tried to model the spectrum of PG 1543+489 using a partial-covering model [model (f)] instead of a reflection component. This spectral fitting provides a statistically better result ($\chi^2$/d.o.f. = 445.1/440), a steep photon index ($\Gamma = 2.78 \pm 0.04$) and a covering fraction (i.e. the fraction of the nuclear source covered by the absorber) of $0.53^{+0.12}_{-0.10}$. The derived rest-frame column density ($N_H = 2.12^{+0.91}_{-0.80} \times 10^{23} \text{ cm}^{-2}$) appears difficult to reconcile with the apparent lack of extinction in the optical/ultraviolet (UV) spectrum of PG 1543+489 (e.g. Baskin & Laor 2005) but could be explained assuming a dust-to-gas ratio largely below the Galactic value (e.g. Maiolino et al. 2001). In this model, where the absorber must be close to the X-ray emitting region, possibly within the sublimation radius (thus explaining the low extinction), we would expect to observe significant variations in the parameters of the partial covering model over the three observations used in the spectral fitting. Although the spectral constraints from the individual observations are relatively poor, we find that in the archival observation and in the two 2007 observations the column density is $N_H = 3.2^{+3.5}_{-2.0} \times 10^{23} \text{ cm}^{-2}$ and $N_H = 1.2^{+1.3}_{-0.5} \times 10^{23} \text{ cm}^{-2}$, and the covering fraction 0.59 $\pm$ 0.27 and 0.53 $\pm$ 0.11, respectively. Therefore, within the statistical uncertainties, it seems that no significant variations in the absorber occur over a rest-frame time-scale of $\approx 3$ yr, which might cast some doubts on the physical reliability of this model. On the other hand, in the framework of the light-bending model, a reduced variability of the reflection component with respect to the continuum can be explained. If the continuum variability is not entirely intrinsic but is mainly due to changes in the location of the primary source of hard X-rays, light-bending effects close to the central massive black hole predict little variability of the spectral components reprocessed by the accretion disc (Miniutti & Fabian 2004).

In all the models mentioned above, the inclusion of a narrow ($\sigma = 10 \text{ eV}$) iron Kα line at 6.4 keV (rest-frame EW $< 450 \text{ eV}$) is not required by the data.

### 3 DISCUSSION

From a broad-band perspective, the combined analysis of EPIC and OM data of PG 1543+489 allows us a simultaneous study of its SED, parametrized by $\alpha_{\text{ox}}$, the slope of the hypothetical power law connecting the rest-frame wavelengths of 2500 Å and 2 keV and defined as

$$\alpha_{\text{ox}} = \frac{\log(f_{2\text{keV}}/f_{2500\text{\AA}})}{\log(v_{2\text{keV}}/v_{2500\text{\AA}})},$$

where $f_{2\text{keV}}$ and $f_{2500\text{\AA}}$ are the flux densities at rest-frame 2 keV and 2500 Å, respectively. In this regard, the derived $\alpha_{\text{ox}}$ values ($\sim -1.64$ for the archival observation, $\sim -1.45$ and $\sim -1.47$ for the 2007 observations analysed in Section 2.3) are fully consistent with those expected on the basis of the known anticorrelation between this spectral index and the 2500-Å luminosity (using the most up-to-date parameterization reported in Just et al. 2007). Therefore, at least in the UV-to-X-ray energy range, the broad-band properties of PG 1543+489 do not appear to be unusual.

From an X-ray point of view, the spectrum of PG 1543+489 appears characterized by a steep photon index and a strongly skewed, relativistic iron line, both accounted for by a ionized reflection model. There are indications that the former spectral result may be related to the high accretion rate of the source (Aoki et al. 2005; Baskin & Laor 2005), as actually found in most of the NLS1s and NLQs (e.g. Boroson 2002). As a further support to such indication, Shemmer et al. (2006), using a sample of 30 quasars up to redshift $\approx 2$, have shown that the photon index depends primarily on the $U$-band flux density, since this filter at $z = 0.40$ approximately samples the rest-frame wavelength of 2500 Å, while for the archival observation, the flux density obtained from the UVMD filter was extrapolated assuming the UV slope reported in Matsumoto et al. (2006); our result is consistent with Matsumoto et al. findings.

### 2.4 Long-term X-ray flux variability of PG 1543+489

In the attempt to evaluate the long-term behaviour of PG 1543+489, we analysed the ASCA on-axis observation of this quasar (see George et al. 2000), using the products available at the Tartarus data base$^4$, and an off-axis observation with Chandra, coupled with the three XMM–Newton observations presented in the previous section. From ASCA to the archival XMM–Newton observation, over a time-scale of $\approx 6$ yr ($\approx 4.3$ yr in the source rest frame), the 2–10 keV source flux has changed by a factor of $3.5$ (from $5.1\times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$ in the ASCA observation to $1.7\times 10^{-13}$ erg cm$^{-2}$ s$^{-1}$ in the first XMM–Newton observation, which corresponds to a rest-frame 2–10 keV luminosity of $1.1\times 10^{44}$ erg s$^{-1}$), with no evidence for X-ray spectral variability. Unfortunately, the 2002 Chandra observation does not provide enough counts ($\approx 220$) for a detailed X-ray spectral fitting, and the spectral analysis is limited in the energy range $\approx 0.5$–4 keV. Within the uncertainties, the constraints on the photon index obtained by Chandra are consistent with our XMM–Newton results, and the extrapolated 2–10 keV flux is intermediate between those measured by ASCA and XMM–Newton (archival observation). In 2007, the source 2–10 keV flux increased to $2.7\times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$ (OBS_ID=0505050201) and by a similar factor in the 0.5–2 keV band, and became $2.4\times 10^{-11}$ erg cm$^{-2}$ s$^{-1}$ in the last analysed XMM–Newton observation (OBS_ID=0505050701).
the source accretion rate; this correlation is more robust than that obtained for $\Gamma$ versus FWHM(H$\beta$), i.e. sources with steeper X-ray spectra (both in the soft and hard X-rays) have typically narrower H$\beta$ emission lines (e.g. Laor et al. 1994; Brandt et al. 1997; Laor et al. 1997), as actually observed also in PG 1543+489.

As a non-secondary effect/indication of the high accretion rate of this source, there is evidence for a strong blueshift and asymmetric profile in the [O iii] 5007 Å and C iv 1459 Å emission lines (Aoki et al. 2005; Baskin & Laor 2005); a high-ionization, optically thin wind, propagating outward the broad-line region and caused by the radiation pressure of the quasar represents a viable explanation (Marziani et al. 2003b), as well as a scenario whereby the narrow-line region clouds are entrained in a decelerating wind (Komossa et al. 2008). This result finds support from the dependence of the amount of blueshift versus the source optical luminosity in a sample of quasars with similar properties to those of PG 1543+489 (Aoki et al. 2005).

The presence of a relativistic iron line places this quasar among the small number of luminous AGN where such feature has been detected so far. In addition to those Seyfert-like AGN that ‘historically’ (i.e. since ASCA and RXTE observations) were known to doubtlessly show relativistic iron lines (e.g. MCG–6–30–15, Tanaka et al. 1995; NGC 3516, Nandra et al. 1999; IRAS 18325–5926, Iwasawa et al. 1996; MCG–5–23–16, Weaver, Kroll & Pier 1998), over the last few years XMM–Newton and Chandra good-quality spectral data have allowed detailed investigations of the presence of relativistic features in a sizable number of AGN (e.g. Porquet & Reeves 2003; Miniutti & Fabian 2006; Piconcelli et al. 2006; Porquet 2006 and references therein; Miniutti et al. 2006; Krumpe et al. 2007; Longinotti et al. 2007; Schartel et al. 2007), also at moderately high redshifts (e.g. Comastri, Brusa & Civano 2004; Chartas et al. 2007), and have enabled relevant statistical analyses (Guainazzi, Bianchi & Dovciak 2006; Nandra et al. 2006; Inoue, Terashima & Ho 2007). From these studies, ≈40 per cent of the XMM–Newton AGN with more than 10000 counts in the 2–10 keV band have broad iron features (Guainazzi et al. 2006), although the situation may be more complex and foresee the presence of complex absorption (e.g. Nandra et al. 2007).

Although further data may be required to provide better constraints on the ionization of the continuum and, possibly, on the line parameters, it is interesting to note that this is the first time that such line is detected in PG 1543+489: the ASCA observation showed only marginal evidence for the presence of a broad iron line, probably due to the higher background level of the ASCA observation and lower effective area of its instruments. We also note that the line was not detected in the analysis of the archival XMM–Newton observation carried out by Brocksopp et al. (2006) and Matsumoto et al. (2006), with an upper limit to a narrow iron Kα line being 800 eV according to the latter authors. It seems plausible that the data reduction procedure and cleaning performed by the other authors are different from ours. This possibility is confirmed by the much larger statistical uncertainties that Brocksopp et al. (2006) quote in their spectral fittings than those presented in this work (Section 2.3), probably caused by a less effective subtraction of the flaring-background intervals (as apparent from their fig. 1) and by our adopted strategy to enhance the S/N in the hard band via the source extraction radius optimization (Section 2.3). Moreover, the availability of multiple XMM–Newton observations of PG 1543+489 showing a similar spectral behaviour provides further support to our results.

A possible cause of concern is the large EW of the iron line (EW = 3.1 ± 0.8 keV in the source rest frame), much larger than typically observed in local Seyfert galaxies and quasars and among the largest EWs ever found in AGN (see, for comparison, Fig. 2 of Guainazzi et al. 2006). Plausible explanations include (1) significant iron overabundance, (2) reflection-dominated spectrum which, even with solar Fe abundance, yields to a self-consistent line EW with respect to its own reflection continuum, (3) matter partially covering the X-ray source. Although iron overabundance is present in the optical spectrum of PG 1543+489 (Aoki et al. 2005), the fact that the iron line intensity grows logarithmically with the iron abundance (Matt, Fabian & Reynolds 1997) would require an extremely high abundance to account for the observed iron Kα line EW. Therefore, this hypothesis appears unlikely.

The second hypothesis, the possibility that the X-ray spectrum is reflection-dominated, appears the most plausible, although more accurate spectral data are required to provide a more robust and convincing support to it. According to recent literature, the presence of a reflection-dominated spectrum can be associated with strong light-bending effects at work close to the black hole (Miniutti & Fabian 2004). In this model, strong light bending is expected if the primary source is located close to the central black hole and illuminates the inner regions of the accretion disc. In this situation, almost all of the radiation emitted by the source is bent on to the disc rather than escaping to the observer. In general, the relative fraction of reflected versus observed power-law flux depends on the height of the source above the disc (e.g. see Miniutti et al. 2003; Miniutti & Fabian 2004; Crummy et al. 2005; Ponti et al. 2006). Given the good fit to the data obtained using a ionized reflection model convolved with a relativistic blurring kernel from the Laor (1991) code, the source of X-ray photons should be located very close to the black hole during the XMM–Newton observations presented here. This reflection model predicts broad and strong iron lines (also see Dabrowski & Lasenby 2001 for details) when the source is in a relatively low X-ray flux regime, which could be the case for PG 1543+489 in the XMM–Newton observations (see Section 2.4); furthermore, it has provided a plausible explanation for the spectral properties of some NLS1s showing reflection-dominated spectra and, possibly, strong iron lines (e.g. Miniutti & Fabian 2004; Porquet 2006), for the luminous NLQ PHL 1092 (Gallo et al. 2004a) and, recently, for the soft excess of many PG quasars (Crummy et al. 2006). As recently pointed out by Merloni et al. (2006), reflection-dominated spectra could also be produced in a disc consisting of an inhomogeneously heated plasma (hot phase) pervaded by small dense clumps (cold phase), which intercept most of the photons coming from the hot phase. Therefore, while in this model the reflection is related to the clumpy and inhomogeneous nature of the inner disc, in the light-bending model it is due to general relativistic effects (for details, see Malzac, Merloni & Suebsuwong 2006), although any further sign of such effects on the X-ray emission is probably not visible because of the still limited statistics. Unfortunately, the current X-ray data do not allow us to discriminate between these two models.

From a statistical and physical basis, also a partial-covering model (third hypothesis) provides a good description of the X-ray spectral complexities of PG 1543+489. Under some assumptions for the absorbing medium (see Section 2.3), it is possible to reproduce the optical properties of PG 1543+489, which shows a blue continuum and features related to the broad-line region, with no indications for significant extinction. In this model, if the absorber is in form of clouds close to the nuclear engine, X-ray spectral variability is likely to take place due to orbital motions of the matter around the black hole and/or outflow phenomena (see Section 1). The lack of any appreciable variations in the properties of the absorber over the time-scale probed by our observations suggests that
this model is less likely than the light bending model; however, we note that the large uncertainties in the measurements derived from the individual observations prevent us from obtaining a firm conclusion on this issue.

Over the next years, with the availability of extended observations of NLS1s and NLQs, it would be interesting to understand whether some sort of connection exists between the presence of ionized reflection (related to the closeness of the source of X-rays to the black hole in the light-bending model), the accretion rate of the AGN and winds/outflows phenomena.

4 SUMMARY

We have analysed an archival plus proprietary XMM–Newton observations of PG 1543+489 (probing a rest-frame time-scale of ≈3 yr), a NLQ at z = 0.400. We found evidence for a steep continuum and a relativistic iron Kα emission line, which are both accounted for in the framework of either ionized reflection or partial-covering of the source. The large EW (3.1 ± 0.8 keV in the source rest frame) of the line would be naturally explained in the context of ionized reflection if the source of X-ray photons is very close to the accreting black hole, thus being subject to strong gravity effects; however, a partial covering model cannot be ruled out on the basis of the current data. The steep X-ray spectrum is possibly related to the high accretion rate of PG 1543+489, as suggested by recent studies on quasars and, likely, by the strong outflow and asymmetric profiles measured in the [O iii] 5007 Å and C iv 1549 Å emission lines, which make of PG 1543+489 one of the most intriguing quasars in the PG sample and a valuable scientific case for future investigations.
