Abstract

Recent studies inspired by results from random matrix theory [1, 2, 3] found that covariance matrices determined from empirical financial time series appear to contain such a high amount of noise that their structure can essentially be regarded as random. This seems, however, to be in contradiction with the fundamental role played by covariance matrices in finance, which constitute the pillars of modern investment theory and have also gained industry-wide applications in risk management. Our paper is an attempt to resolve this embarrassing paradox. The key observation is that the effect of noise strongly depends on the ratio \( r = \frac{n}{T} \), where \( n \) is the size of the portfolio and \( T \) the length of the available time series. On the basis of numerical experiments and analytic results for some toy portfolio models we show that for relatively large values of \( r \) (e.g. 0.6) noise does, indeed, have the pronounced effect suggested by [1, 2, 3] and illustrated later by [4, 5] in a portfolio optimization context, while for smaller \( r \) (around 0.2 or below), the error due to noise drops to acceptable levels. Since the length of available time series is for obvious reasons limited in any practical application, any bound imposed on the noise-induced error translates into a bound on the size of the portfolio. In a related set of experiments we find that the effect of noise depends also on whether the problem arises in asset allocation or in a risk measurement context: if covariance matrices are used simply for measuring the risk of portfolios with a fixed composition rather than as inputs to optimization, the effect of noise on the measured risk may become very small.

Keywords: noisy covariance matrices, random matrix theory, portfolio optimization, risk management

1 Introduction

Covariance matrices of financial returns play a crucial role in several branches of finance such as investment theory, capital allocation or risk management. For example, these matrices are the key input parameters to Markowitz’s classical portfolio optimization problem [6], which aims at providing a recipe for the composition of a portfolio of assets such that risk (quantified by the standard deviation of the portfolio’s return) is minimized for a given level of expected return. For any practical use of the theory it would therefore be necessary to have reliable estimates for the volatilities and correlations of the returns on the assets making up the portfolio (i.e. for the elements of the covariance matrix), which are usually obtained from historical return series. However, the finite length $T$ of the empirical time series inevitably leads to the appearance of noise (measurement error) in the covariance matrix estimates. It is clear that this noise becomes stronger and stronger with increasing portfolio size $n$, until at a certain $n$ one overexploits the available information to such a degree that the positive definiteness of the covariance matrix (and with that the meaning of the whole exercise) is lost.

This long known difficulty has been put into a new light by [1, 2, 3] where the problem has been approached from the point of view of random matrix theory. These studies have shown that empirical correlation matrices deduced from financial return series contain such a high amount of noise that, apart from a few large eigenvalues and the corresponding eigenvectors, their structure can essentially be regarded as random. In [2], e.g., it is reported that about 94% of the spectrum of correlation matrices determined from return series on the S&P 500 stocks can be fitted by that of a random matrix. One wonders how, under such circumstances, covariance matrices can be of any use in finance. Indeed, in [2] the authors conclude that “Markowitz’s portfolio optimization scheme based on a purely historical determination of the correlation matrix is inadequate”.

Two subsequent studies [4, 5] found that the risk level of optimized portfolios could be improved if prior to optimization one filtered out the lower part of the eigenvalue spectrum of the covariance matrix, thereby removing the noise (at least partially). In both of these studies, portfolios have been optimized by using the covariance matrix extracted from the first half of the available empirical sample, while risk was measured as the standard deviation of the return on these portfolios in the second half of the sample. [4, 5] found a significant discrepancy between “predicted” risk (as given by the standard deviation of the optimal portfolio in the first half of the sample) and “realized” risk (given by its actual realization in the second half), although this discrepancy could be diminished by the use of the filtering technique. While these results suggest potential applications of random matrix theory, they also reinforce the doubts about the usefulness of empirical covariance matrices.

On the other hand, Markowitz’s theory is one of the pillars of present day finance. For example, the Capital Asset Pricing Model (CAPM), which plays a kind of benchmark role in portfolio management, was inspired by Markowitz’s approach; various
techniques of capital allocation are based on similar ideas. Furthermore, over the years, covariance matrices have found industry-wide applications also in risk management. For example, RiskMetrics [7], which is perhaps the most widely accepted methodology for measuring market risk, uses covariance matrices as its fundamental inputs. The presence of such a high degree of noise in empirical covariance matrices as suggested by [1, 2, 3, 4, 5] and the fact that these matrices are so widely utilized in the financial industry constitute an intriguing paradox.

The motivation for our previous study [8] stemmed from this context. In addition to the noise due to the finite length of time series, real data always contain additional sources of error (non-stationarity, changes in the composition of the portfolio, in regulation, in fundamental market conditions, etc.). In order to get rid of these parasitic effects, we based our analysis on data artificially generated from some toy models. This procedure offers a major advantage in that the “true” parameters of the underlying stochastic process, hence also the statistics of the covariance matrix are exactly known. Furthermore, with a comparison to empirical data in mind, where the determination of expected returns becomes an additional source of uncertainty, we confined ourselves to the study of the minimal risk portfolio. Our main finding was that for parameter values typically encountered in practice the “true” risk of the minimum-risk portfolio determined in the presence of noise (i.e. based on the covariance matrix deduced from finite time series) is usually no more that 10–15% higher than that of the portfolio determined from the “true” covariance matrix.

In the present work we continue and extend our previous analysis, but keep to the same toy-model-based approach as before. These models can be treated both numerically and, in the limit when \( n \) and \( T \) go to infinity with \( r = n/T = \text{fixed} \), analytically. Varying the ratio \( r = n/T \) we show that the difference between “predicted” and “realized” risk can, indeed, reach the high values found in [4, 5] when \( r \) is chosen as large as in those papers, but decreases significantly for smaller values of this ratio. This observation eliminates the apparent contradiction between [4, 5] and our earlier results [8]. Since in the simulation framework we know the exact process, not only its finite realizations, we can compare the “predicted” and “realized” risk to the “true” risk of the portfolio. We find that “realized” risk is a good proxy for “true” risk in all cases of practical importance and that “predicted” risk is always below, whereas “realized” risk is above the “true” risk. For asymptotically small values of \( n/T \) all the noise vanishes, but the value of \( T \) is, for evident reasons, limited in any practical application, therefore any bound one would like to impose on the effect of noise translates, in fact, into a constraint on the portfolio size \( n \).

Regarding one other aspect of the problem, we find that the effect of noise is very different depending on whether we wish to optimize the portfolio, or merely want to measure the risk of a given, fixed portfolio. While in the former case the effect of noise remains important up to relatively small values of \( n/T \), in the latter case it becomes insignificant much sooner. This explains why covariance matrices could have remained a fundamental risk management tool even to date.
2 Results and Discussion

We consider the following simplified version of the classical portfolio optimization problem: the portfolio variance \( \sum_{i,j=1}^{n} w_i \sigma_{ij} w_j \) is to be minimized under the budget constraint \( \sum_{i=1}^{n} w_i = 1 \), where \( w_i \) denotes the weight of asset \( i \) in the portfolio and \( \sigma_{ij} \) represents the covariance matrix of returns. One could, of course, impose additional constraints (e.g. the usual one on the return), but this simplified form provides the most convenient laboratory to test the effect of noise, since it eliminates the uncertainty coming from the determination of expected returns. The solution to the optimization problem can then be found using the method of Lagrange multipliers, and after some trivial algebra one obtains for the weights of the optimal portfolio:

\[
w_i^* = \frac{\sum_{j=1}^{n} \sigma_{ij}^{-1}}{\sum_{j,k=1}^{n} \sigma_{jk}^{-1}}.
\] (1)

Starting with a given “noiseless” covariance matrix \( \sigma_{ij}^{(0)} \) we generate “noisy” covariance matrices \( \sigma_{ij}^{(1)} \) as

\[
\sigma_{ij}^{(1)} = \frac{1}{T} \sum_{t=1}^{T} y_{it} y_{jt},
\] (2)

where \( y_{it} = \sum_{j=1}^{n} L_{ij} x_{jt} \), with \( x_{jt} \sim \text{i.i.d. N}(0, 1) \) and \( L_{ij} \) the Cholesky decomposition of the matrix \( \sigma_{ij}^{(0)} \) (a lower triangular matrix which satisfies \( \sum_{k=1}^{n} L_{ik} L_{jk} = \sigma_{ij}^{(0)} \), or \( L^T L = \sigma^{(0)} \)). In this way we obtain “return series” \( y_{it} \) that have a distribution characterized by the “true” covariance matrix \( \sigma_{ij}^{(0)} \), while \( \sigma_{ij}^{(1)} \) will correspond to the “empirical” covariance matrix. Of course, in the limit \( T \to \infty \) the noise disappears and \( \sigma_{ij}^{(1)} \to \sigma_{ij}^{(0)} \).

The main advantage of this simulation approach over empirical studies is that the “true” covariance matrix is exactly known.

For our experiments we choose two simple forms for \( \sigma_{ij}^{(0)} \). First, we perform our simulations with the simplest possible form for \( \sigma_{ij}^{(0)} \), the identity matrix (Model I). In order to move a little closer to the observed structures, however, we also perform experiments with matrices \( \sigma_{ij}^{(0)} \) which have one eigenvalue chosen to be about 25 times larger than the rest and with the corresponding eigenvector (representing the “whole market”) in the direction of \((1, 1, \ldots, 1)\), while keeping the simplicity of the identity matrix in the other directions (Model II). This latter is meant to be a caricature of the covariance matrices deduced from financial return series (see [2, 3]).

In order to see the effect of noise on the portfolio optimization problem we compare the square roots of the following quantities:

1. \( \sum_{i,j=1}^{n} w_i^{(0)*} \sigma_{ij}^{(0)} w_j^{(0)*} \), the “true” risk of the optimal portfolio without noise, where \( w_i^{(0)*} \) denotes the solution to the optimization problem without noise;

2. \( \sum_{i,j=1}^{n} w_i^{(1)*} \sigma_{ij}^{(0)} w_j^{(1)*} \), the “true” risk of the optimal portfolio determined in the case of noise, where \( w_i^{(1)*} \) denotes the solution to the optimization problem in the presence of noise;
3. $\sum_{i,j=1}^{n} w_i^{(1)} \sigma_{ij} w_j^{(1)}$, the “predicted” risk (cf. [4, 5]), that is the risk that can be observed if the optimization is based on a return series of length $T$;

4. $\sum_{i,j=1}^{n} w_i^{(1)} \sigma_{ij} w_j^{(2)}$, the “realized” risk (cf. [4, 5]), that is the risk that would be observed if the portfolio were held one more period of length $T$, where $\sigma_{ij}^{(2)}$ is the covariance matrix calculated from the returns in the second period.

To facilitate comparison, we calculate the ratios of the square roots of the three latter quantities to the first one, and denote these ratios by $q_0$, $q_1$ and $q_2$, respectively. That is $q_0$, $q_1$ and $q_2$ represent the “true”, “predicted” resp. the “realized” risk, expressed in units of the “true” risk in the absence of noise. For both model covariance matrices $\sigma_{ij}^{(0)}$, we perform simulations for different values of the number of assets $n$ and length of the time series $T$. For each given $n$ and $T$, we generate several return series and covariance matrices, and each time we calculate the corresponding ratios $q_0$, $q_1$ and $q_2$. Finally, we calculate the mean and standard deviation of these quantities for given $n$ and $T$.

Table 1: “True”, “predicted”, and “realized” risk for different values of the number of assets $n$ and length of time series $T$ (the figures in parentheses denote standard deviations).

| Mod. | $n$  | $T$  | $q_0$          | $q_1$ | $q_2$          | $q_2/q_0$ | $q_2/q_1$ |
|------|------|------|----------------|-------|----------------|-----------|-----------|
| I    | 100  | 600  | 1.09 (0.01)    | 0.92 (0.03) | 1.09 (0.03)    | 1.00 (0.03) | 1.19 (0.05) |
| I    | 500  | 3000 | 1.09 (0.01)    | 0.91 (0.01) | 1.10 (0.02)    | 1.00 (0.01) | 1.20 (0.03) |
| I    | 500  | 1500 | 1.22 (0.01)    | 0.81 (0.01) | 1.22 (0.02)    | 1.00 (0.01) | 1.49 (0.03) |
| I    | 500  | 750  | 1.73 (0.07)    | 0.57 (0.02) | 1.74 (0.07)    | 1.00 (0.02) | 3.00 (0.16) |
| II   | 500  | 3000 | 1.09 (0.01)    | 0.91 (0.01) | 1.10 (0.01)    | 1.00 (0.01) | 1.20 (0.02) |
| II   | 500  | 750  | 1.72 (0.06)    | 0.58 (0.02) | 1.72 (0.08)    | 1.00 (0.02) | 2.97 (0.17) |

The results of our simulations are given in Table 1. It can be seen that $q_0$ is higher than 1 for all values of $n$ and $T$, as one would expect since the “optimal” portfolio obtained from the “noisy” covariance matrix must be less efficient than the one obtained from the “true” covariance matrix. It is also clear that $q_2$ is always very close to $q_0$, which suggests that “realized” risk can be used as a good proxy for the “true” risk when the “true” covariance matrix is not known. This is the very case in empirical studies, and therefore on the basis of our simulation results we can expect that the values obtained for “realized” risk for example in [4, 5] must indeed be close to the true risk figures.

This, unfortunately, fails to be true for the predicted risk. As seen from the table, $q_1$ is always smaller than $q_0$ (or $q_2$). Since $q_1$ (actually the numerator of the fraction that determines $q_1$) is the only risk figure that can be obtained in a framework when one sets up the optimal portfolio based on a finite sample of returns (i.e. when the true covariance matrix is unknown) and $q_0$ is the “true” risk of the obtained portfolio, in such cases one will end up with underestimating risk. Therefore, optimization in the presence of noise will bias risk measurement and lead to the underestimation of
risk of the optimal portfolio. These conclusions are in perfect qualitative agreement with those in [4, 5]. The important point is the magnitude of the effect, however. It is obvious, and also born out by Table 1, that the effect of noise should decrease with \( r = n/T \), i.e. the risk measures \( q_0 \) and \( q_1 \) should converge to 1 as the length of the time series goes to infinity, with the size of the portfolio kept constant.

For \( T, n \to \infty \) and \( r = n/T = \text{fixed} \) one can, in fact, calculate \( q_0 \) and \( q_1 \) analytically. Since the variance of a portfolio is a rotation invariant scalar, it can be evaluated in the principal axis system of the covariance matrix. In terms of the eigenvalue density

\[
\rho(\lambda) = \frac{1}{2\pi r} \sqrt{\frac{(\lambda_+ - \lambda)(\lambda - \lambda_-)}{\lambda}}
\]  

(3)
of the covariance matrix (see [2]), where \( \lambda_\pm = (1 \pm \sqrt{r})^2 \), \( q_0 \) can be written [10] as

\[
q_0 = \frac{\sqrt{\int \rho(\lambda)/\lambda^2 \, d\lambda}}{\int \rho(\lambda)/\lambda \, d\lambda}.
\]

(4)

Simple integration yields \( q_0 = 1/\sqrt{1-r} \). Similarly, for \( q_1 \) one can obtain \( q_1 = \sqrt{1-r} \). It is easy to verify that these asymptotic formulae fit the simulation results very well. Also note that, as we have argued in [8], when we have sufficient information about the portfolio, i.e. when \( n/T \) is small enough (such as for example in the first two rows in the table, or less), then \( q_0 \) is not dramatically higher that 1, i.e. the inefficiency introduced by noise may not necessarily be very large. We have repeated our numerical experiments for Model II and obtained very similar results (see the last two rows of Table 1).

In our view, the main message to be inferred from the above analysis is the bound it implies for the noise-induced error. According to the above formulae for \( q_0 \) and \( q_1 \), within the framework of our toy Model I the error in the risk estimate is about \( r/2 \) for small \( r \) (and we know that predicted risk is always smaller than the true risk!) As a result of inevitable additional imperfections (non-stationarity, deviation from normal statistics, etc.), the error in the risk estimate of real-life portfolios can only be larger than this, so \( r/2 \) can be viewed as a lower bound on the error. Conversely, if we set a value for the acceptable error, we have a bound on the ratio \( n/T \). Since the length of meaningful time series is always limited (by changes in the composition of the portfolio, changes in the regulatory environment, in market conditions, etc.), this means that we have an upper bound on the size of the portfolio whose risk can be estimated with the pre-determined error. The filtering technique proposed in [4, 5] can then be regarded as a tool to break through this upper bound.

Next, we compare our simulation results with results obtained for covariance matrices determined from empirical return series. To accomplish this, we use daily return series on 400 major US stocks during the period 1991–1996 (1200 observations for each stock). The data have been extracted from the the same dataset as in [4-6]. Four

---

1 We thank J.-P. Bouchaud and L. Laloux for making the dataset available for us.
non-overlapping samples of $n = 100$ stocks were created and divided into two periods of length $T = 600$. For each sample, the first period was used for optimization and the calculation of “predicted” risk, while the second period for determining “realized” risk. We found that the ratio of “predicted” and “realized” risk $q_2/q_1$ was $1.36 \pm 0.07$, somewhat higher than in our simulations for the same $n$ and $T$ (1.19). To see whether this was caused simply by an increase in volatility in the second period or not, we repeated our calculations with swapping the two periods in each sample, but we obtained similar results ($1.44 \pm 0.08$). The additional bias in $q_2/q_1$ could be caused, however, by volatility dynamics (e.g. conditional heteroskedasticity). In order to diminish the effect of possible inhomogeneities in volatility we divided the sample such that every other value from the return series was allocated to the first “period” while the rest to the second. In this case we obtained $q_2/q_1 = 1.22 \pm 0.06$, a result in line with our simulations. In view of these latter findings, the results obtained e.g. in [4] can be easily understood. In the empirical example of [4] with $n = 406$ and $T = 654$, “realized” risk exceeded “predicted” risk by a factor of around 3, which seems reasonable if one takes into account that for this case the simulations, or the theory of the toy model, predict a value of 2.6.

Finally, we studied the effect of noise on portfolios which were selected somehow independently from the covariance matrix data. For example, one could invest in equal proportions in each asset, or concentrate the portfolio to a few assets (e.g. stocks from one single sector). We analyze therefore the implications of noise on the risk measurement of portfolios whose weights are determined independently of the covariance matrix data. Let us consider a portfolio with weights $w_i$ fixed ($\sum_{i=1}^{n} w_i = 1$). In a simulation setup in which covariance matrices are generated as before, we compare the “true” risk of the portfolio (as measured by the square root of $\sum_{i,j=1}^{n} w_i \sigma_{ij}^{(0)} w_j$) to the “observed” risk (deduced from $\sum_{i,j=1}^{n} w_i \sigma_{ij}^{(1)} w_j$), and let $q$ denote the ratio of the second to the first. Our simulations show that for large enough time series length $T$, this quantity is very close to 1, no matter whether the number of assets $n$ is small or large. For example, in the case in which the “true” covariance matrix is the $n \times n$ identity matrix and the weights $w_i$ are chosen to be $1/n$ for all $i$, for $T = 100$ and $n = 10$, one obtains $q = 1.00 \pm 0.07$, for $T = 1000$ and $n = 10$, $q = 1.00 \pm 0.02$, while for $T = 100$ and $n = 100$, $q = 1.00 \pm 0.07$ (the mean is 1 and the standard deviation is of the order of $1/\sqrt{T}$). The results obtained for other choices of the covariance matrix $\sigma_{ij}^{(0)}$ and of the weights $w_i$ are similar, therefore we are led to the conclusion that the effect of randomness on the risk estimate of portfolios with fixed weights is very limited.
3 Conclusion

In this paper we have studied the implications of noisy covariance matrices on portfolio optimization and risk management. The main motivation for this analysis was the apparent contradiction between results obtained on the basis of random matrix theory and the fact that covariance matrices are so widely utilized for investment or risk management purposes. Using a simulation-based approach we have shown that for parameter values typically encountered in practice the effect of noise on the risk of the optimal portfolio may not necessarily be as large as one might expect on the basis of the results of [1, 2, 3]. The large discrepancy between “predicted” and “realized” risk obtained in [4, 5] can be explained by the low values of $T/n$ used in these studies; for larger $T/n$ the effect becomes much smaller. The analytic formulae derived in this paper provide a lower bound on the effect of noise, or, conversely, an upper bound on the size of the portfolios whose risk can be estimated with a prescribed error. Finally, we have shown that for portfolios with weights determined independently from the covariance matrix data, the effect of noise on the risk measurement process is quite small.

A very interesting topic for further research would be to analyze the magnitude of these effects for portfolios constructed by techniques really used in practice, for example by an asset manager or hedge fund, since these methods often combine sophisticated optimization schemes with more subjective expert assessments.

Acknowledgements

We are extremely grateful to G. Papp and M. Nowak for pointing out the way to analytically calculate $q_0$ and for valuable discussions. We are also obliged to J.-P. Bouchaud and L. Laloux for sharing with us some of their data and for discussions. This work has been supported by the Hungarian National Science Found OTKA, Grant No. T 034835.
