Rare $B$ Meson Decays at the Tevatron

Walter Hopkins

Cornell University

Abstract. Rare $B$ meson decays are an excellent probe for beyond the Standard Model physics. Two very sensitive processes are the $b \to s\mu^+\mu^−$ and $B^0_{d,s} \to \mu^+\mu^−$ decays. We report recent results at a center of mass energy of $\sqrt{s} = 1.96$ TeV from CDF II using 7 fb$^{-1}$ at the Fermilab Tevatron Collider.

1 Introduction: $b \to s\mu^+\mu^−$ decays

$b \to s\mu^+\mu^−$ decays are flavor changing neutral current (FCNC) processes that can only occur through higher order box or penguin amplitudes in the Standard Model. New physics can be probed by measuring various combinations of their decay rates. One of the most sensitive observables is the forward-backward asymmetry of the muons ($A_{FB}$) as a function of the squared di-muon mass.

Decays of interest are $B^+ \to \mu^+\mu^−K^*$, $B^0_{d,s} \to \mu^+\mu^−K^{*0}(892)$, $B^0_{d,s} \to \mu^+\mu^−\phi$, $B^+ \to \mu^+\mu^−K^{*+}$, $B^0_{d,s} \to \mu^+\mu^−K_s$, $\Lambda_b \to \mu^+\mu^−\Lambda$. The CDF analysis that uses 6.8 fb$^{-1}$ of data is described here [1], [2].

1.1 Analysis Method

1.1.1 Branching Ratio Measurement

Branching ratios for the $b \to s\mu^+\mu^−$ decays are measured relative to normalization modes, where the two muons originate from a $J/\psi$ decay. For the event reconstruction CDF requires two muons with a transverse momentum ($p_T$) greater than either 1.5 GeV/c, 2.0 GeV/c, or 3.0 GeV/c depending on the muon trigger. The six modes are then reconstructed where the $K^{*0}$ ($892)$ is reconstructed from $K^{*0}$ ($892)$ $\to K^+\pi^-$, the $\phi$ from $\phi \to K^+K^-$, the $K^{*+}$ from $K^{*+}$ $\to K_s\pi^+$, the $K_s$ from $K_s \to \pi^+\pi^-$, and the $\Lambda$ from $\Lambda \to p\pi^-$. To avoid contamination from resonant modes such as the $J/\psi$ and $\psi'$, candidates with di-mu mass near these resonances are rejected.

The events then have to meet loose preselection requirements before an artificial neural network (NN), which combines multiple discriminating variables into one variable, is applied. Signal is modeled with $p_T$-reweighted Pythia signal Monte Carlo simulations (MC). The reweighting is done by comparing the MC $p_T$ distribution with that of the normalization modes. The background is modeled by sampling the $b$ hadron ($H_b$) mass sideband regions.

The final signal yield is obtained by an unbinned maximum likelihood fit to the $H_b$ mass distribution. The probability distribution function (PDF) of the signal is parametrized with two Gaussian with different means while the the background PDF is described here by a first or second order polynomial. Peaking background contributions are subtracted from the fit results for the signal yields. The only significant peaking contribution is cross-talk among the observed signal MC yields. The final branching ratios are calculated as follows:

$$B(H_b \to h\mu^+\mu^-) = \frac{N_{NN, h\mu^+\mu^-}}{N_{NN, loose, h\mu^+\mu^-}} \frac{1}{B(J/\psi)} \frac{\mathcal{B}(J/\psi \to h\mu^+\mu^-)}{\mathcal{B}(J/\psi \to \mu^+\mu^-)},$$

where $H_b$ signifies the $B^0_d$, $B^0_s$, or $\Lambda_b$ and $h$ represents $K^{*0}(892)$, $K^*$, $K^{*+}$, $K_s$, $\Lambda$, or $\phi$, $N_{NN, h\mu^+\mu^-}$ and $N_{NN, loose, h\mu^+\mu^-}$ are the yields after the optimal NN selection, $\mathcal{B}(J/\psi)$ is the relative efficiency of the loose selection cuts, and $\mathcal{B}(J/\psi)$ is the NN cut efficiency on the loosely-selected events. The NN is not applied to the normalization mode because the signal/purity and size is sufficient with the loose selection cuts. The NN cut efficiency are obtained from signal MC.

The three leading systematics are the systematics on the efficiency, $\mathcal{B}(H_b \to J/\psi)$, and background PDF. The main sources within the efficiency systematic errors are the MC reweighing and the the trigger turn on. The total systematics for the $B^+ \to \mu^+\mu^−K^*$, $B^0_{d,s} \to \mu^+\mu^−K^{*0}(892)$, $B^0_{d,s} \to \mu^+\mu^−\phi$, $B^+ \to \mu^+\mu^−K^{*+}$, $B^0_{d,s} \to \mu^+\mu^−K_s$, $\Lambda_b \to \mu^+\mu^−\Lambda$ are 5%, 6%, 32%, 8%, 6%, and 32%, respectively.

1.1.2 Forward-Backward Asymmetry Measurement

For the $B^0_{d,s} \to \mu^+\mu^−K^{*0}(892)$ and $B^+ \to \mu^+\mu^−K^*$ ($B^0_{d,s} \to \mu^+\mu^−K^{*0}(892)$ and $B^+ \to \mu^+\mu^−K^*$ combined fit for increased sensitivity) decays the forward-backward asymmetry ($A_{FB}$), the $K^*$ longitudinal polarization ($F_L$), the transverse polarization asymmetry ($A_T^\perp$), as well as the triple product asymmetry of the transverse polarizations ($A_T^{3\perp}$) are measured. For $B^+ \to \mu^+\mu^−K^*$ only $A_{FB}$ is measured. The $A_{FB}$ and $F_L$ angular quantities are extracted from $\cos \theta_{\mu}$, the cosine of the helicity angle between the $\mu^+$ ($\mu^−$) momentum vector and the opposite of $B$ ($\bar{B}$) meson momen-
tum vector in the di-muon rest frame, and \( \cos \theta_K \), the cosine of the angle between kaon momentum and the opposite of the \( B \) meson momentum vector in the \( K^{\pm}(892) \) rest frame. \( A_{K}^{\pm} \) and \( A_{0}^{\pm} \) are extracted from \( \phi \), where the angle \( \phi \) is the angle between the two decay planes of the di-muon pair and \( K - \pi \) decay pair. \( B \) decay amplitudes are calculated using operator product expansion and Wilson coefficients. There are many non-SM predictions for \( A_{FB} \) from models with different Wilson coefficients [3].

The angular measurements are extracted using an unbinned maximum likelihood fit containing \( B \) mass shape signal and background PDF’s as well as signal and background angular shape PDF’s. The mass shape PDF’s are divided into several di-muon mass bins and are described as 25 bin histograms. The combinatorial background PDF is taken from the \( B \) meson higher sideband. The angular acceptances are also described as 25 bin histograms and are derived from phase space signal MC.

As a control \( A_{FB} \) and \( F_1 \) are fitted to \( B^0_s \rightarrow J/\psi K^{\pm}(892) \) and \( A_{FB} \) only to \( B^+ \rightarrow J/\psi K^+ \). This cross check yielded measurements that were consistent with other measurements.

The dominant systematic uncertainties for all angular measurements are the signal fraction and \( B \) mass shape uncertainties. This uncertainty is assessed by varying the signal fraction and shape parameters by \( \pm 1 \sigma \) (statistical uncertainty) when performing the \( B \) mass fit.

1.2 Results

The resulting yield for the six decays are shown in Figure [1] All measured branching ratios agree with previous measured values as well as theoretical predictions. CDF reports the first observation of \( \Lambda_b \rightarrow \mu^+\mu^-\Lambda \) with a significance of \( \sim 6 \sigma \) and a measured branching ratio of \( \mathcal{B}(\Lambda_b \rightarrow \mu^+\mu^-\Lambda) = (1.73 \pm 0.42) \text{stat} \pm (0.55) \text{syst}) \times 10^{-6} \).

The results of the angular measurements for the combined \( B \rightarrow \mu^+\mu^-K^* \) fit are shown in Figure [2]. They are consistent with theory predictions and competitive with the results from the B-factories.

2 Introduction: \( B^0_{s,d} \rightarrow \mu^+\mu^- \) decays

\( B^0_{s,d} \rightarrow \mu^+\mu^- \) are FCNC decays that are highly suppressed by the SM. The SM predictions for these branching fractions are \( \mathcal{B}(B^0_s \rightarrow \mu^+\mu^-) = (3.2 \pm 0.2) \times 10^{-9} \) and \( \mathcal{B}(B^0_d \rightarrow \mu^+\mu^-) = (1.00 \pm 0.11) \times 10^{-10} \) [3]. These predictions are one order of magnitude smaller than the current experimental sensitivity. Previous bounds from the CDF collaboration, based on 3.7 \( \text{fb}^{-1} \) of integrated luminosity, are \( \mathcal{B}(B^0_s \rightarrow \mu^+\mu^-) < 4.3 \times 10^{-8} \) and \( \mathcal{B}(B^0_d \rightarrow \mu^+\mu^-) < 7.6 \times 10^{-9} \) at 95% C.L. [5].

Enhancements to the rate of \( B^0_{s,d} \rightarrow \mu^+\mu^- \) decays occur in a variety of different new-physics models. In supersymmetric (SUSY) models, new particles can increase \( \mathcal{B}(B^0 \rightarrow \mu^+\mu^-) \) by several orders of magnitude at large \( \tan \beta \). In the minimal supersymmetric standard model (MSSM), the enhancement is proportional to \( \tan^6 \beta \). Global analysis including all existing experimental constraints suggest that the large \( \tan \beta \) region is of interest [6,7,8,9].

This document describes the current status from CDF.

2.1 Analysis Method

CDF collects opposite sign muon candidate events using di-muon triggers.

\( B^+ \rightarrow J/\psi K^+ \) events are collected on the same triggers as a relative normalization mode to estimate \( \mathcal{B}(B^0_s \rightarrow \mu^+\mu^-) \) as:

\[
\mathcal{B}(B^0_s \rightarrow \mu^+\mu^-) = \frac{N_{B^0_s}}{\alpha_{B^0_s} \cdot \mathcal{B}(B^0_s \rightarrow J/\psi K^+)} \cdot \frac{\mathcal{B}(J/\psi \rightarrow \mu^+\mu^-)}{\alpha_{B^0_s} \cdot \mathcal{B}(B^0_s \rightarrow J/\psi K^+)} \cdot \mathcal{B}(J/\psi \rightarrow \mu^+\mu^-) \cdot \mathcal{B}(B^0_s \rightarrow J/\psi K^+),
\]

where \( N_{B^0_s} \) is the number of candidate \( B^0_s \rightarrow \mu^+\mu^- \) events, \( \alpha_{B^0_s} \) is the geometric and kinematic acceptance of the di-muon trigger for \( B^0_s \rightarrow \mu^+\mu^- \) decays, \( \alpha_{B^0_s} \) is the total efficiency (including trigger, reconstruction and analysis requirements) for \( B^0_s \rightarrow \mu^+\mu^- \) events in the acceptance, with \( \alpha_{B^0_s} \cdot \mathcal{B}(B^0_s \rightarrow J/\psi K^+) \) similarly defined for \( B^+ \rightarrow J/\psi K^+ \) decays. The ratio \( f_d/f_s \) accounts for the different b-quark fragmentation probabilities and is \( (0.402 \pm 0.013)/(0.112 \pm 0.013) = 3.589 \pm 0.374 \), including the (anti-)correlation between the uncertainties [10]. The final two terms are the relevant branching ratios \( \mathcal{B}(B^+ \rightarrow J/\psi K^+) \cdot \mathcal{B}(J/\psi \rightarrow \mu^+\mu^-) = (1.01 \pm 0.03) \times 10^{-3} \cdot 5.93 \pm 0.06) \times 10^{-2} = (6.01 \pm 0.21) \times 10^{-5} [10]. \)
2.2 Signal and Background Properties

The signal candidates are fully reconstructed events with a secondary vertex due to the long lifetime (~450μm) of the $B_d$ meson. Signal events will have a primary-to-secondary vertex vector that is aligned with the $B_d$ candidate momentum vector. Another property of signal events that is unique is that they are very isolated (few tracks near the muon tracks) due to the hard B fragmentation.

Background events tend to be partially reconstructed and be shorter lived than signal. They also have a softer $p_T$ spectrum, higher activity of tracks, and misaligned primary-to-secondary vertex and momentum vectors. The combinatorial background consists of sequential semi-leptonic decays ($b \rightarrow c\nu X \rightarrow \mu^+\mu^- X$), double semi-leptonic decay ($bb \rightarrow \mu^+\mu^- XX$), continuum di-muon events, as well as fake+fake and fake+fake events. The expected number of combinatorial background events in the signal window is estimated by extrapolating the number of events in the sideband regions to the signal window using a first order polynomial fit.

The peaking background from two-body hadronic $B$ decays is also evaluated. These backgrounds are about a factor ten smaller in the $B_d$ signal region than the combinatorial background and need to be estimated separately. The dominant contributions to this source of background are the decays of $B^0_s$ and $B^0 \rightarrow h^+h^-$ final states, where $h$ or $h'$ can be either $π^+$ or $K^*$ and are misreconstructed (fake muons).

2.3 Analysis Improvements and Signal Discrimination

CDF has updated their search with an improved analysis and significantly more (+3.2 fb$^{-1}$) data. The forward muon acceptance (left Figure 3) has been increased and the neural network has been improved to achieve twice the background reduction (right Figure 3). Additionally the neural network has been extensively tested for mass bias. The peaking background prediction has also been improved. The central-forward (CF) channel of the analysis has increased in statistics by ~15% resulting in a total increase for both channels of ~7%.

The final NN network consists of 14 input variables. Extensive cross checks were done to demonstrate the 14-variable network does not sculpt the di-muon invariant mass distribution. Figure 4 shows the correlation across the $M_{\mu^+\mu^-}$ mass range. No significant correlations are seen.
2.4 Control Samples for Background Estimates

The background estimate procedure is cross checked on four independent background samples:

- OS:- opposite-sign muon pairs, which pass the baseline and vertex cuts and have a negative lifetime;
- SS+: same-sign muon pairs, which pass looser baseline and vertex cuts and have a positive lifetime;
- SS:- same-sign muon pairs, which pass looser baseline and vertex cuts and have a negative lifetime;
- FM+/: opposite-sign fake-muon pairs, at least one leg of which is required to fail the muon ID requirement, passing looser baseline and vertex cuts for both positive and negative lifetimes.

These are representative of various background contributions and thus are excellent control regions to test the methodology. The resulting background-only pseudo-experiments by allowing them to float within Gaussian constraints. The observed events for the background predictions and yields an observed limit of 95% (90%) C.L. in the top part of Figure 5. The data is consistent with the background estimates are ruled out. Problems with the NN are also evident. Additionally a p-value of 23.5% is set at 5 × 10^{-8}.

In the B_{s}^{0} search region the data exceed the background prediction in bins with NN > 0.97. The bottom part of Figure 5 contains the breakdown of the expected background and actual observation for the individual NN and mass bins for the B_{s}^{0} → μ^{+}μ^{-} search. The source of the data excess in the 0.970 < NN < 0.987 bin of the B_{s}^{0} signal region was investigated. The same events, same fits, and same methodologies are used for both the B_{d}^{0} and B_{s}^{0} searches. Because the data in the B_{d}^{0} search region shows no excess, problems with the background estimates are ruled out. Problems with the NN are ruled out by the many studies performed. The most plausible remaining explanation is that this is a statistical fluctuation.

The p-value for the background-only hypothesis is 0.27%. Additionally a p-value of 1.92% is also calculated assuming the SM+background hypothesis.

A χ^{2} fit is used to determine the B(B_{d}^{0} → μ^{+}μ^{-}) most consistent with the data in the B_{d}^{0} search region. A central value and 68% C.L. is calculated at B(B_{d}^{0} → μ^{+}μ^{-}) = (1.8^{+1.1}_{-0.9}) × 10^{-8}. Additionally a bound at 90% (95%) C.L. on the branching fraction of B_{d}^{0} → μ^{+}μ^{-} is set at 5.4 × 10^{-9} < B(B_{d}^{0} → μ^{+}μ^{-}) < 3.9 × 10^{-8} (2.8 × 10^{-9} < B(B_{d}^{0} → μ^{+}μ^{-}) < 4.4 × 10^{-8}).

Finally, upper limits at 95% (90%) C.L. of B(B_{d}^{0} → μ^{+}μ^{-}) < 4.0 × 10^{-8} (3.5 × 10^{-8}) are set with the CLs methodology.

2.5 Results

The observed events for the B_{d}^{0} → μ^{+}μ^{-} search are shown in the top part of Figure 5. The data is consistent with the background prediction and yields an observed limit of B(B_{d}^{0} → μ^{+}μ^{-}) < 6.0 (5.0) × 10^{-8} at 95% (90%) C.L.

An ensemble of background-only pseudo-experiments are employed to estimate the significance as a p-value. The effects of systematic uncertainties are included in the pseudo-experiments by allowing them to float within Gaussian constraints. The resulting background-only p-value for the B_{d}^{0} → μ^{+}μ^{-} search is 23.5%.

In the B_{s}^{0} search region the data exceed the background prediction in bins with NN > 0.97. The bottom part of Figure 5 contains the breakdown of the expected background and actual observation for the individual NN and mass bins for the B_{s}^{0} → μ^{+}μ^{-} search. The source of the data excess in the 0.970 < NN < 0.987 bin of the B_{s}^{0} signal region was investigated. The same events, same fits, and same methodologies are used for both the B_{d}^{0} and B_{s}^{0} searches. Because the data in the B_{d}^{0} search region shows no excess, problems with the background estimates are ruled out. Problems with the NN are ruled out by the many studies performed. The most plausible remaining explanation is that this is a statistical fluctuation.

The p-value for the background-only hypothesis is 0.27%. Additionally a p-value of 1.92% is also calculated assuming the SM+background hypothesis.

A χ^{2} fit is used to determine the B(B_{d}^{0} → μ^{+}μ^{-}) most consistent with the data in the B_{d}^{0} search region. A central value and 68% C.L. is calculated at B(B_{d}^{0} → μ^{+}μ^{-}) = (1.8^{+1.1}_{-0.9}) × 10^{-8}. Additionally a bound at 90% (95%) C.L. on the branching fraction of B_{d}^{0} → μ^{+}μ^{-} is set at 5.4 × 10^{-9} < B(B_{d}^{0} → μ^{+}μ^{-}) < 3.9 × 10^{-8} (2.8 × 10^{-9} < B(B_{d}^{0} → μ^{+}μ^{-}) < 4.4 × 10^{-8}).

Finally, upper limits at 95% (90%) C.L. of B(B_{d}^{0} → μ^{+}μ^{-}) < 4.0 × 10^{-8} (3.5 × 10^{-8}) are set with the CLs methodology.

Fig. 5. Top: Background estimates (light gray), systematic error on background estimates (hashed area), Poisson error on the data (error bars on points), and data for the B_{s}^{0} signal window. Bottom: Similar plots for B_{d}^{0} with the addition of the SM expectations (dark gray). The data is divided into 8 NN bins, of which lowest 5 NN bins are combined into one bin for both figure, 5 mass bins, and two muon topologies (CC and CF).

3 Conclusion

FCNC decays are a powerful probe for New Physics and CDF continues to lead the searches in the B sector. The B_{d}^{0} → μ^{+}μ^{-} analysis has yielded the first two sided bound to B(B_{d}^{0} → μ^{+}μ^{-}) and will be updated with the full CDF Run II data set. CDF also has the first observation of A_{0} → μ^{+}μ^{-}Λ^{+} as well as angular measurements that compete and agree with the B-factory results. A_{0}^{+} and A_{0}^{0} are also measured for the first time for B → μ^{+}μ^{-}K^{*} decays.
