We study the dynamics of electrons in monolayer Molybdenum Disulfide (MoS$_2$), in the absence as well as presence of a transverse magnetic field. Considering the initial electronic wave function to be a Gaussian wave packet, we calculate the time dependent expectation value of position and velocity operators. In the absence of the magnetic field, the time dependent average values of position and velocity show damped oscillations dependent on the width of the wave packet. In the presence of a transverse magnetic field, the wave packet amplitude shows oscillatory behaviour over short timescales associated with classical cyclotron orbit, followed by the phenomena of spontaneous collapse and revival over larger timescales. We relate the timescales of these effects and our results can be useful for the interpretation of experiments with trapped ions.

I. INTRODUCTION

In recent years, the interest in atomically thin two-dimensional materials with honeycomb lattice structure have grown considerably after the realization of single dimensional materials with honeycomb lattice structure of two inequivalent K points. Apart from graphene there are other crystals like silicene$^3$,4, Boron Nitride$^5$, monolayer group-VI dichalcogenides MX$_2$ (M=Mo, W and X=S, Se) etc. which also have a honeycomb lattice structure. Currently, the dichalcogenide material MoS$_2$ (Molybdenum disulphide)$^6$ has drawn lot of attention due to its unique electronic$^7$, optical$^8,9$ and transport$^{10}$ properties. Like graphene, the Brillouin zone of monolayer MoS$_2$ consists of two inequivalent K points. However, unlike graphene MoS$_2$ monolayer is a direct band-gap semiconductor with a gap$^{11}$ of the order of 1.6 eV. Since the band gap lies in the visible frequency range, it is also suitable for optoelectronic device applications.

In 1930, Schrödinger$^{12}$ pointed out that a relativistic electron in vacuum, described by the Dirac equation, exhibits rapid oscillations, which are manifested in the time evolution of physical observables such as position, current and spin angular momentum. This phenomenon, also known as zitterbewegung (ZB), occurs due to the superposition$^{13}$ of electron and hole counterparts of the Dirac spinor. Experimental observation of ZB has been illusive till date due to the large oscillation frequency $\omega_z \approx 10^{21}$ Hz and the small oscillation amplitude $\lambda_z \approx 10^{-13}$ m. In addition, it was shown by Lock$^{14}$ that the ZB oscillations of Dirac electrons described by a wave packet decay with time.

Zitterbewegung is not necessarily a relativistic effect. It can also occur in non-relativistic electrons, e.g., in crystalline solids$^{15,16}$, and is a direct consequence of coupling between the energy eigenstates of the system. In 2005, Zawadzki$^{17}$ showed that the oscillation amplitude of ZB is enhanced by factor of 10$^4$ in narrow gap semiconductors. In the same year, Schliemann et. al.$^{18}$ studied the wave packet dynamics and ZB in spin-orbit coupled two-dimensional electron gas formed at the heterojunctions. These works triggered a large number of theoretical investigations of wave packet dynamics and ZB in various condensed matter systems$^{19-24}$, including carbon nanotubes$^{25}$, graphene$^{26-34}$, superconductors$^{22}$ and hole Luttinger systems$^{35}$. The wave packet dynamics and ZB have also been studied in other systems such as 2D photonic crystal$^{36}$, 2D sonic crystal$^{37}$, and spin-orbit coupled atomic gases$^{38}$. The relation between amplitude of ZB oscillations and Berry connection was explicitly shown in Refs. [38–40]. Recently experimental observations of ZB phenomenon has been reported in trapped ion systems$^{41}$ as well as in$^{87}$Rb Bose Einstein condensates$^{42,43}$.

In this Article we study the dynamics of electrons described by an initial Gaussian wave packet in monolayer MoS$_2$. In the absence of an external magnetic field, we find the expected behaviour of oscillations and decay of the wave packet amplitude, which is manifested in the the expectation values of physical observables such as position and velocity. In the presence of a perpendicular magnetic field, i.e., for a discrete Landau level spectrum, the long term dynamics of the wave packet shows the phenomena of spontaneous collapse and revival of the wave packet amplitude, which is a direct example of the so called quantum recurrence theorem$^{45}$.

This Article is organized as follows. In section II we discuss low energy Hamiltonian, the electronic eigenstates and eigen-energies of a MoS$_2$ monolayer. We then study the dynamics of physical observables such as the position and velocity, and find that these are characterized by particular oscillation frequencies and decay constant. In section III we explore the dynamics of a Gaussian wave packet in the presence of a transverse magnetic field. Starting with the Landau level spectrum and the corresponding wave functions of MoS$_2$ monolayer, we calculate the long term time evolution of physical observables of an initial Gaussian wave packet. We find the phenomena of spontaneous collapse and consequent revival here, for which the associated timescales follow from the expansion of the wave packet energy around some dominant Landau level$^{44,46}$. We summarize our work in section IV.
II. DYNAMICS OF A GAUSSIAN WAVE PACKET

A. Hamiltonian

The single particle low-energy Hamiltonian of monolayer MoS$_2$, in the vicinity of each of the two valley’s at the edges of the hexagonal first Brillouin zone (BZ), denoted by $K$ and $K'$ respectively, is given by\textsuperscript{47,48}

$$H = \{\hbar v_F (\zeta q_x \tau_x + q_y \tau_y) + \Delta_0 \tau_z \} \otimes 1_x + H_{\text{so}} ,$$

where $v_F$ is the Fermi velocity, $q = (q_x, q_y)$ is the wave vector of electron around $K$ points, and $\Delta_0$ is the ‘direct’ band gap at the corner points of hexagonal BZ. Here $\zeta = +1$ denotes the valley $K$ and $\zeta = -1$ denotes the $K'$ valley. The set of Pauli matrices given by $\tau_i$ and $\sigma_i$ act on the conduction band-valance band space and the electron-spin space, respectively, and the symbol $\otimes$ denotes the direct product. In Eq. (1) the term $H_{\text{so}}$ represents the Hamiltonian corresponding to the spin-orbit interaction, which can be described by the following expression

$$H_{\text{so}} = \zeta \Delta_{\text{so}} \frac{1_x + \tau_x}{2} \otimes \sigma_z + \zeta \Delta_{\text{so}}' \frac{1_x - \tau_x}{2} \otimes \sigma_z ,$$

where $2\Delta_{\text{so}} (2\Delta_{\text{so}}')$ is the spin-orbit gap in the conduction (valence) band. Typically in MoS$_2$, $\Delta_{\text{so}} \approx 3$ meV and $\Delta_{\text{so}}' \approx 150$ meV so that the gap $\Delta_{\text{so}}$ can be neglected and the effective SOI gap can be approximated as $\Delta_{\text{so}} \approx \Delta_{\text{so}}'$. We note that even though $H_{\text{so}}$ is different in the two valleys, it is a constant for each valley, and the system is equivalent to two spin-resolved Dirac Hamiltonians given by,

$$H = \hbar v_F (\zeta q_x \tau_x + q_y \tau_y) + \Delta_{\text{so}} \tau_z + \Delta_{\text{so}}' \frac{1_x \pm \tau_x}{2} ,$$

where the spin and valley dependent gap is given by $\Delta_{\text{so}} = \Delta_0 - \zeta \Delta_{\text{so}}/2$ with $s = \pm 1$ denoting the up-spin and down-spin electron respectively. The last term of constant energy, $(\Delta_{\text{so}}' + \Delta_{\text{so}}')/2$, plays no physical role and will be neglected henceforth. We emphasise here that Eq. (3), is a spin and valley resolved Hamiltonian whose low energy spectrum coincides with the massive Dirac equation in two dimensions - with a gap that is dependent on the spin and valley index.

The energy eigenvalues of the spin and valley resolved Hamiltonian, in Eq. (3), are given by

$$\epsilon^\lambda_q = \lambda \sqrt{(\hbar v_F q)^2 + \Delta_{\text{so}}^2} ,$$

where $\lambda = \pm 1$ denotes the conduction and valance bands respectively. The corresponding eigen-functions are given by

$$\psi^\lambda_q (r) = \frac{e^{i q \cdot r}}{2\sqrt{2\pi}} \left( \frac{1}{\lambda e^{-i \theta}} \right) ,$$

where $\tan \theta = q_y/q_x$.

In the rest of the Article, we will ‘inject’ an electronic Gaussian wave function in monolayer MoS$_2$, and study its dynamics. A generic wave packet for MoS$_2$ will have a eight-component spinor form, but since the spin and valley parts of the low energy Hamiltonian are decoupled from each other, each of the two-component spinors (corresponding to conduction and valance bands) evolve independently of each other. Henceforth we only consider the evolution of ‘spin and valley polarized’ two-component spinor.

B. Time evolution of physical observables

To describe the time evolution of electron wave packets we start with an electronic Gaussian wave packet (i.e., a spinor wave packet having the conduction band component as unity and no valance band component),

$$\Psi (r, 0) = \frac{1}{2\pi} \int d^2 q \ a_q \ e^{i q \cdot r} \begin{pmatrix} 1 \\ 0 \end{pmatrix} ,$$

where $a_q = \frac{d}{\sqrt{2\pi}} e^{-\frac{|q-q_0|^2}{2}}$ is a Gaussian wave packet of width $d$, which is initially centered at $q = q_0$, in the momentum space. Note that $d$ should be greater than the lattice spacing, so that $\Psi$ is a smooth enveloping function. The wave packet at a later time $t$ can be found by operating the time evolution operator, $U(t) = e^{-i\mathcal{H}t}/\mathcal{H}$, on the initial state i.e., $\Psi (r, t) = U(t)\Psi (r, 0)$. Straightforward calculation gives the spinor wave packet at a later time $t$ to be of the following form in the Fourier space:

$$\begin{pmatrix} \Phi_1 (q, t) \\ \Phi_2 (q, t) \end{pmatrix} = \begin{pmatrix} \cos (\Omega_q t) - i \frac{\Delta_{\text{so}}}{h} \sin (\Omega_q t) \\ -i \frac{\Delta_{\text{so}}'}{h} (\zeta q_x + i q_y) \sin (\Omega_q t) \end{pmatrix} ,$$

where $h\Omega_q = \sqrt{\Delta_{\text{so}}^2 + (\hbar v_F q)^2}$ is half of the difference between the two energy states of the conduction and valance bands, i.e., $\epsilon_q$ and $\epsilon_{q'}$, respectively. The real space spinor components, are now simply given by $[\Psi_1 (r, t), \Psi_2 (r, t)] = \int d^2 q \ e^{i q \cdot r} [\Phi_1 (q, t), \Phi_2 (q, t)]$.

The expectation value of position operator can now be calculated using the momentum representation of the position operator: $r_{\text{op}} = i \nabla_q$, and is given by the following equation,

$$\langle r(t) \rangle = i \int d^2 q \ \Phi^\dagger (q, t) \nabla_q \Phi (q, t) .$$

Straightforward calculation yields

$$\langle r(t) \rangle = \langle r(0) \rangle + \frac{\Delta_{\text{so}} v_F^2}{h} \int d^2 q \ |a_q|^2 \left( t - \frac{1}{2\Omega_q} \sin (2\Omega_q t) \right) q - \frac{v_F^2}{2} \int d^2 q \ |a_q|^2 \Omega_q^2 \nabla_q \theta \left\{ 1 - \cos (2\Omega_q t) \right\} .$$
For the specific choice of $a_0$ adopted here, it is easy to show that $\langle x(0) \rangle = 0$. For definiteness, in the rest of the manuscript we choose, $\zeta = 1$ and $s = 1$, and define $\Delta \equiv \Delta_{\zeta s}$. Now, by considering the initial momentum of the Gaussian wave packet along $y$ direction (i.e., $q_{0x} = 0$ and $q_{0y} = q_0$) one can obtain the expectation value of $x$ component of the position operator (‘transverse’ to the initial momentum of the wave packet) to be

$$\langle x(t) \rangle = \int_0^\infty dq_0 \eta_i \left[ 1 - \cos \left( \frac{2v_F t}{d} \tilde{\Omega}_q \right) \right],$$

where we have defined

$$\eta_i = de^{-q_0^2 d^2 \tilde{\Omega}_q^2} e^{-\tilde{q}^2} I_1(2q_0 \tilde{q})$$

and $I_1(x)$ is the (first order) modified Bessel function of second kind and we have defined the dimensionless parameters: $\tilde{q} = qd$, $\tilde{\Delta} = (d/hv_F) \Delta$ and $\tilde{\Omega}_q = (d/v_F) \Omega_q$. Note that for $q \gg 1$, the modified Bessel function of the second kind has the following asymptotic form, $I_n(x) = e^n/\sqrt{2\pi x}$.

The integrations over $\tilde{q}$ in Eq. (10) is performed numerically, and the time dependence of the position expectation value is shown in Fig. 1a). Two prominent features observed in Fig. 1a) are, the oscillations or ZB in the expectation value and the decay of the oscillation amplitude of ZB. The oscillation timescale of the ZB can be extracted, by working in the $q_0d \gg 1$ limit where one can use the asymptotic form of the modified Bessel function given above, and noting that in Eq. (11), $\eta_i \approx de^{-(d-q_0d)^2 \tilde{\Omega}_q^2}/(\tilde{\Omega}_q^2 \sqrt{4\pi q_0d})$. This implies that the integrand in Eq. (10) is peaked around $q_0d$ and consequently the oscillation timescale of ZB is given by

$$\tau_{zb} = \frac{\pi d}{v_F \sqrt{\tilde{\Delta}^2 + q_0^2 d^2}}.$$  \hspace{1cm} (12)

The decay in the oscillation amplitude of ZB, occurs due to the interference of different frequencies, corresponding to different $\tilde{q}$ in Eq. (10). This decay timescale can be obtained from Eq. (10), by using the exponential form of $\cos(2v_F t \tilde{\Omega}_q/d) = \text{Re} \left[ e^{i(2v_F t \tilde{\Omega}_q/d)} \right]$ to include the time dependence in the exponential terms. Straightforward algebra gives the decay of the oscillation amplitude to be of the form: $e^{-\tau^2/\tau_d^2}$, where

$$\tau_d^{-2} = \frac{v_F^2 q_0^2 d^2}{d^2 q_0^2 d^2 + \Delta^2}.$$  \hspace{1cm} (13)

As a check of our estimate we note that Eq. (13) fits very well to the exact numerical results — see the solid black lines in Fig. 1a).

The $y$ component of the position operator (‘longitudinal’ to the initial momentum of the wave packet) is given by

$$\langle y(t) \rangle = 2\tilde{\Delta} \int_0^\infty dq_0 \eta_i \left[ \frac{v_F t}{d} - \frac{1}{2\tilde{\Omega}_q} \sin \left( \frac{2v_F t}{d} \tilde{\Omega}_q \right) \right],$$

where $\eta_i$ was defined in Eq. (11). As expected due to finite initial momentum in the $y$ direction, the centre of the wave packet moves in the $y$ direction with a constant velocity. The ZB oscillations occur around the centre of the moving wave packet on the timescale given by $\tau_{zb}$, but with reduced amplitude, due to the presence of $\tilde{\Omega}_q$ in the denominator of the oscillating term — see Fig. 1b). Eventually, for $t \gg \tau_{zb}$, the oscillating contribution to $\langle y \rangle$ becomes vanishingly small in comparison to the term linearly increasing with time.

The components of the velocity operator can be obtained from the Heisenberg equation of motion: $i\hbar \dot{v}_i = [x_i, \hat{H}]$. The expectation value of the velocity components can now be calculated by using the spinor wave functions in Eq. (7), and are given by

$$\langle x(t) \rangle = \int_0^\infty dq_0 \eta_i \sin \left( \frac{2v_F t}{d} \tilde{\Omega}_q \right),$$

and

$$\langle y(t) \rangle = \frac{2v_F}{d} \tilde{\Delta} \langle x(t) \rangle.$$  \hspace{1cm} (16)
As a check of our calculations, we note that the equation for the autocorrelation function is now given by

\[ A(t) = \sum_{n=-\infty}^{\infty} |c_n|^2 e^{i t/\hbar} (\epsilon_{n0} + (n-n_0)\epsilon'_{n0} + (n-n_0)^2\epsilon''_{n0}/2 + \ldots) \]

and each term in the exponential defines a characteristic timescale via,

\[ \tau_{\text{osc}} = \frac{2\pi\hbar}{\epsilon_{n_0}} \quad \tau_{\text{cl}} = \frac{2\pi\hbar}{|\epsilon'_{n_0}|} \quad \text{and} \quad \tau_{\text{rev}} = \frac{4\pi\hbar}{|\epsilon''_{n_0}|}. \]

The timescale \( \tau_{\text{osc}} \), is an intrinsic ‘zitterbewegung’ time scale, which leads to a \( n \)-independent overall phase which induces no interference in the wave packet and is thus unimportant for studying long term dynamics of the system. At the ‘classical’ cyclotron time \( \tau_{\text{cl}} \), the wave packet comes back to the initial position and the autocorrelation function approximately reaches its initial value. For the ‘quantum’ revival of the wave packet the terms proportional to the second derivative in the energy should be in multiples of \( 2\pi \), and this leads to additional recurrences of the initial wave packet at time \( t = \tau_{\text{rev}} \). This revival hierarchy continues to higher orders. Moreover, at times that are rational fractions of \( \tau_{\text{rev}} \), the wave packet undergoes fractional revivals, i.e., a sequence of reconstructions, which give regular well-localised structure of the wave packet amplitude. The fractional revival at \( \tau_{\text{rev}}/2 \) is particularly interesting, as it represents the initial wave packet shifted by half of the classical period \( \tau_{\text{cl}}/2 \).

In addition to these, for \( \tau_{\text{cl}} < t < \tau_{\text{rev}} \), the terms quadratic in \( n - n_0 \) lead to the dephasing and consequently collapse of the initial wave packet over timescale given by, \( \tau_{\text{coll}} = \tau_{\text{rev}}/(\Delta n)^2 \). The exact expressions for these timescales for the present case of monolayer MoS\(_2\) are given in the next subsection. See Ref. [50] for a detailed review regarding these timescales.

### B. Evolution of a Gaussian wave packet

We now proceed to calculate the time evolution of the initial wave packet. To obtain the Landau level spectrum of MoS\(_2\) in a transverse magnetic field, we work with Landau gauge \( \mathbf{A} = (-By, 0, 0) \) for the vector potential. Now making the Landau-Peierls substitution \( \mathbf{q} \rightarrow \mathbf{q} + \mathbf{eA}/\hbar \) in Eq. (3), the spin and valley resolved single-particle Hamiltonian is given by

\[ H_B = \hbar v_F \left[ \zeta \left( q_x - \frac{eB}{\hbar} y \right) \tau_x + q_y \tau_y \right] + \Delta \tau_z. \]

The energy spectrum of the Hamiltonian in Eq. (20), which forms quantized Landau levels, is given by

\[ \epsilon_n = \lambda \sqrt{\Delta^2 + \varepsilon^2 n}, \]

where \( \varepsilon = \sqrt{2}\hbar v_F/l_c \) with \( l_c = \sqrt{\hbar/eB} \) being the magnetic length and \( \lambda = \pm 1 \). The corresponding eigen-
vectors for \( \lambda = \pm 1 \) branches are given by

\[
\psi^+_{n,q}(x,y) = \frac{e^{iq_xx}}{\sqrt{2\pi A_n}} \left( -D_n\phi_{n-1}(y-y_c) \right), \tag{22}
\]

\[
\psi^-_{n,q}(x,y) = \frac{e^{iq_xx}}{\sqrt{2\pi A_n}} \left( \phi_{n-1}(y-y_c) D_n\phi_n(y-y_c) \right), \tag{23}
\]

where

\[
\phi_n(y-y_c) = N_n e^{-\frac{(y-y_c)^2}{2l_c^2}} H_n((y-y_c)/l_c),
\]

\[
D_n = (\Delta + \sqrt{\Delta^2 + \epsilon^2 n})/(\epsilon\sqrt{n}),
\]

\[
A_n = 1 + D_n^2,
\]

with \( N_n = (\sqrt{\pi} 2^n n! l_c)^{-1/2} \), \( H_n \) is the Hermite polynomial of order \( n \), and finally \( y_c = q_x l_c^2 \). Note that for \( n = 0 \) there is only one state with energy

\[
\epsilon_0 = \Delta,
\]

and eigen function

\[
\psi_0(x,y) = \frac{e^{iq_xx}}{\sqrt{2\pi}} \left( \frac{0}{\phi_0(y-y_c)} \right). \tag{26}
\]

We now calculate the expectation values of position and velocity operator in presence of a finite transverse magnetic field following the Green’s function approach. Since \( q_0 \) is no longer a good quantum number of the system, it is simpler to work in the position representation for the initial wave packet (unlike the \( B = 0 \) case where it was easier to work with the Fourier representation of the initial wave packet).

We consider the initial state to be a coherent state, i.e., a Gaussian wave packet of the following form,

\[
\Psi(r,0) = \frac{1}{\sqrt{\pi l_c}} \exp \left( -\frac{r^2}{2l_c^2} + i q_0 x \right) \begin{pmatrix} 1 \\ 0 \end{pmatrix}, \tag{27}
\]

where \( q_0 \) is the initial momentum along the \( x \) direction and the width of the Gaussian wave packet is considered to be equal to the magnetic length, \( l_c \). The wave packet at a later time \( t \) can be written as

\[
\Psi(r,t) = \int G(r,r',t)\Psi(r',0)dr', \tag{28}
\]

where \( G(r,r',t) \) is the Green’s function which is a \( 2 \times 2 \) matrix in this case. The matrix elements of the Green’s functions are given by

\[
G_{\mu,\nu}(r,r',t) = \sum_{n,\lambda} \int dq_x \psi^\lambda_{n,q_x}(r,t)\psi^\ast_{n,q_x,\mu}(r',0), \tag{29}
\]

where \( \psi^\lambda_{n,q_x} \)'s are given by Eqs. (22)-(23) and \( \psi^\lambda_{n,q_x}(r,t) = \psi^\lambda_{n,q_x}(r,0)e^{-i\epsilon_{\lambda} t/\hbar} \) with \( \epsilon_{\lambda} \) being the energy eigenvalues given in Eq. (21). Since we are injecting the initial wave packet in the \( \lambda = +1 \) branch only, i.e., populating only the positive Landau level energies, [see Eq. (27)], only two elements \( G_{11} \) and \( G_{21} \) of the Green’s function matrix are required to find the components of the wave packet at a later time \( t \). Now \( G_{11} \) and \( G_{21} \) are given by

\[
G_{11}(r,r',t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} dq_x e^{iq_xx(x-x')} \times \sum_{n=0}^{\infty} P_n+1\phi_n(y-y_c)\phi_n(y'-y_c), \tag{30}
\]

and

\[
G_{21}(r,r',t) = \frac{1}{2\pi} \int_{-\infty}^{+\infty} dq_x e^{iq_xx(x-x')} \times \sum_{n=0}^{\infty} Q_{n+1}\phi_n(y-y_c)\phi_n(y'-y_c), \tag{31}
\]

where, \( P_n = \exp(-i\gamma_n t) + 2iA_n^{-1}\sin(\gamma_n t), Q_n = 2iD_n A_n^{-1}\sin(\gamma_n t) \) and \( h\gamma_n = \sqrt{\Delta^2 + \epsilon^2 n} \).

Now inserting Eqs. (30)-(31) into Eq. (28) it is straightforward to obtain the components of the wave packet at a later time \( t \) in the following two component form:

\[
\begin{pmatrix} \Psi_1(r,t) \\ \Psi_2(r,t) \end{pmatrix} = \frac{1}{2\sqrt{2\pi l_c}} \sum_{n=0}^{\infty} \left( -1 \right)^n \int dxuF(x,u)n^u \times \left( \begin{array}{c} P_{n+1}(t)\phi_n(y-y_c) \\ Q_{n+1}(t)\phi_n(y'-y_c) \end{array} \right), \tag{32}
\]

where \( F(x,u) = iux/l_c - (l_c q_0 - u)^2/2 - u^2/4 \) with \( u = q_x l_c \). The expectation values of the components of the position operator can now be calculated from the following equation,

\[
\begin{pmatrix} \langle x(t) \rangle \\ \langle y(t) \rangle \end{pmatrix} = \sum_{i=1}^{2} \int dx dy \sqrt{\Psi^\ast_i(r,t)} \begin{pmatrix} x \\ y \end{pmatrix} \Psi_i(r,t). \tag{33}
\]

The time dependent expectation value of the \( x \) component of the position operator, can be split into two terms, \( \langle x(t) \rangle = \langle x_1(t) \rangle + \langle x_2(t) \rangle \) with \( \langle x_i(t) \rangle = \int dr \sqrt{\Psi^\ast_i(r,t)}x\Psi_i(r,t) \), and \( i = 1,2 \). Now

\[
\langle x_1(t) \rangle = \frac{1}{2\pi l_c^2} \sum_{n,n'} \left( -1 \right)^{n+n'} P_{n'+1}^*P_{n+1} \int dx dy \sqrt{u'ud'} \times e^{F(x,u)+F'(x,u')}x\phi_n(y-y_c)\phi_{n'}(y-y_c'), \tag{34}
\]

where \( y_c' = q_x' l_c^2 = l_c u' \). Note that \( \int dx x e^{i(u-u')x/l_c} = 2\pi i l_c^2 \left[ \partial_u' \delta(u' - u) \right] \). Using the following relation

\[
\int du' g(u') \left[ \partial_{u'} \delta(u' - u) \right] = \frac{dg(u')}{du'} |_{u'=u}, \tag{35}
\]
and doing a lengthy but straightforward calculation we obtain

\[
\langle x_1(t) \rangle = \frac{1}{i\pi} e^{-\frac{4d^2}{\hbar^2}} \sum_{n,n'} (-1)^{n+n'} P_{n+1}' P_{n+1} \int dydu u^{n+n'}
\]

\[
\times e^{-\left(\sqrt{\frac{y}{\hbar}} - \sqrt{\frac{y_0}{\hbar}}\right)^2} \left\{ \left( \frac{n'}{u} + \varphi_0 + \frac{y}{\hbar} - \frac{5u}{2} \right) \phi_{n'} - \sqrt{2n'} \phi_{n'-1} (y - y_c) \right\} \phi_n (y - y_c).
\]

where \( \varphi_0 = q_0 l_c \). The integration over \( \eta \) in Eq. (36) can be done using the orthonormality of Hermite polynomials. Using the result: \( \int_0^\infty dv v^2 e^{-\left(v-\alpha\right)^2} = \sqrt{\pi} H_1(i\alpha)/(2i)^2 \), and the recurrence relations for the Hermite polynomials we finally obtain

\[
\langle x_1(t) \rangle = \sum_{n=0}^\infty \xi_n \text{Im} \left[ P_{n+2}^* P_{n+1}(t) \right],
\]

where we have defined the time independent term,

\[
\xi_n = \frac{i}{3} e^{-\frac{4d^2}{\hbar^2}} \left( \frac{1}{12} \right)^n \frac{1}{n!} H_{2n+1} \left( i\sqrt{\frac{2}{3} \varphi_0} \right).
\]

Following the same procedure as above, we find

\[
\langle x_2(t) \rangle = \sum_{n=0}^\infty \xi_n \sqrt{\frac{n+2}{n+1}} \text{Im} \left[ Q_{n+2}^* Q_{n+1}(t) \right].
\]

The calculations for the expectation value of the \( y \) component of the position operator are less involved, and we obtain the following expression for \( \langle y(t) \rangle = \langle y_1(t) \rangle + \langle y_2(t) \rangle \) with,

\[
\langle y_1(t) \rangle = \sum_{n=0}^\infty \xi_n \left( \text{Re} \left[ P_{n+2}^* P_{n+1} \right] - |P_{n+1}|^2 \right),
\]

and

\[
\langle y_2(t) \rangle = \sum_{n=0}^\infty \xi_n \left( \sqrt{\frac{n+2}{n+1}} \text{Re} \left[ Q_{n+2}^* Q_{n+1} \right] - |Q_{n+1}|^2 \right).
\]

Note that in the above equation we have suppressed the time arguments.

We plot the expectation values of the position operator, given by Eqs. (37)-(41) in Fig. 2 over various timescales. It is useful to have an estimate of the various timescales discussed in the previous subsection for our present case. For monolayer MoS\(_2\), and the choice of the initial Gaussian wave packet in Eq. (27), it is easy to show that \( \eta_0 = \frac{l_c^2}{m} \varphi_0^2/2 \) (for example, see Appendix A of Ref. [32]). Now, using the explicit form of the Landau level energies given by Eq. (21) in Eq. (19), we obtain the timescales for our case to be

\[
\tau_{\text{osc}} = \frac{2\pi \hbar}{\Omega_0}, \quad \tau_{\text{cl}} = \frac{4\pi \hbar \Omega_0}{\varepsilon^2}, \quad \text{and} \quad \tau_{\text{rev}} = \frac{16\pi \hbar \Omega_0^3}{\varepsilon^4},
\]

where we have defined \( \Omega_0 = \sqrt{\Delta^2 + \varepsilon^2} \). Note that for realistic values for MoS\(_2\) parameters — see caption in Fig. 2, these timescales are: \( \tau_{\text{osc}} = 5.10 \text{ fs} \), \( \tau_{\text{cl}} = 428 \text{ ps} \), \( \tau_{\text{rev}} = 71.8 \text{ \( \mu \)s} \), and finally \( \tau_{\text{coll}} = \tau_{\text{rev}}/n_0 = 1.43 \text{ \( \mu \)s} \). Here we have used the fact the the for a coherent state wave packet — see Eq. (27), \( \delta n = \sqrt{n_0} \).

It is noteworthy that the dominant contribution to the sum in Eqs. (37)-(41), arises from the neighbourhood of
where amplitude collapse and revival over clotron orbit oscillations over \( \tau_{cl} \). We also note that in the \( \Delta \rightarrow 0 \), these can also be obtained by differentiating Eq. (43) and the dynamics of relativistic wave packets. Note that Eqs. (45)-(46) reduce to the quasiclassical cyclotron velocities given by

\[
\langle v_x(t) \rangle = \Re (\langle v(t) \rangle), \quad \text{and}, \quad \langle v_y(t) \rangle = \Im (\langle v(t) \rangle),
\]

where

\[
\langle v(t) \rangle = \frac{\sqrt{2}v_F}{t_c} \sum_{n=0}^{\infty} \frac{1}{\sqrt{1+n}} P_n^{n+2} Q_{n+1}.
\]

As in the case of the expectation value of the position operator, for timescales of the order of \( \tau_{cl} \), it can be shown that Eqs. (45)-(46) reduce to the quasiclassical cyclotron velocities given by

\[
\langle v_x(t) \rangle = \sqrt{2\hbar n_0} \ t_c \cos \left( \frac{2\pi t}{\tau_{cl}} \right),
\]

\[
\langle v_y(t) \rangle = \sqrt{2\hbar n_0} \ t_c \sin \left( \frac{2\pi t}{\tau_{cl}} \right).
\]

Similar expressions for velocity in the quasiclassical regime, were also obtained in Ref. [49], where they studied the dynamics of relativistic wave packets. Note that these can also be obtained by differentiating Eq. (43) and Eq. (44) respectively, and are also consistent with Fig. 3a). We also note that in the \( \Delta \rightarrow 0 \) limit, the MoS\(_2\) Landau level spectrum reduces to graphene Landau level spectrum and in the same limit, our result for velocity in Eqs. (45) and (46) are similar to the known results for cyclotron dynamics in graphene in Ref. [31], where they had a different initial wave packet. We plot the expectation value of the velocity operator over various timescales in Fig. 3, and find a behaviour similar to that of the position operator, i.e., quasiclassical cyclotron orbit oscillations over \( \tau_{cl} \), and then wave packet amplitude collapse and revival over \( \tau_{rev}/2 \).

**IV. SUMMARY**

In this Article, we have studied the dynamics of a Gaussian wave packet in monolayer MOS\(_2\), both in the presence of a perpendicular magnetic field and without it. In the absence of a magnetic field, we obtain explicit expressions for the expectation values of the position and velocity operators, which show the expected behaviour of amplitude oscillations (ZB) whose period is given by Eq. (12), and which decay over timescale given by Eq. (13).

For a system with discrete Landau level spectrum (i.e., in the presence of a perpendicular magnetic field), injecting an initial electron wave packet which is peaked around some Landau level energy of MoS\(_2\), we find that the wave packet initially evolves quasiclassically and oscillate with a period of \( \tau_{cl} \) (the cyclotron time-period). However at later times, the wave packet eventually spreads and quantum interference leads to its ‘collapse’, and at even longer times, that are multiples (or rational fractions) of \( \tau_{rev} \).
the wave packet is revived, and the electron position and velocity regains its initial amplitude — again undergoing quasiclassical oscillatory motion. At much shorter timescales, i.e., $\tau_{osc} \ll \tau_{cl} \ll \tau_{rev}$, the electron wave packet undergoes zitterbewegung, but this amplitude is much smaller than that of the quasiclassical cyclotron motion, and is thus suppressed.

We emphasize here that for typical parameters of MoS$_2$, $\tau_{osc} = 5.10$ fs, $\tau_{cl} = 428$ ps, and finally $\tau_{rev} = 71.8$ ns, and as a consequence, wave packet revivals manifested in velocity (and consequently in current) is more accessible to experimental probing. In addition, such dynamics can also be investigated by experimentally studying the nature of electromagnetic multipole radiation and absorption. The results obtained in this Article, can also be useful for the observation of spontaneous collapse and revival in experiments with trapped ions$^{41}$.
