Alkaline wastes

Abstract
Steelmaking wastes stored in landfill, such as slag and spent refractory liners, are often enriched in toxic trace metals (including V). These may become mobile in highly alkaline leachate generated during weathering. Fresh steelmaking waste was characterised using XRD, XRF, and SEM-EDX. Batch leaching tests were performed under aerated, air-excluded and acidified conditions to determine the impact of atmospheric CO₂ and acid addition on leachate chemistry. Phases commonly associated with slag including dicalcium silicate, dicalcium aluminoferrite, a wüstite-like solid solution and free lime were identified, as well as a second group of phases including periclase, corundum and graphite which are representative of refractory linings. During air-excluded leaching, dissolution of free lime and dicalcium silicate results in a high pH, high Ca leachate in which the V concentration is low due to the constraint imposed by Ca₃(VO₄)₂ solubility limits. Under aerated conditions, carbonation lowers the leachate pH and provides a sink for aqueous Ca, allowing higher concentrations of V to accumulate. Below pH 10, leachate is dominated by periclase dissolution and secondary phases including monohydrocalcite and dolomite are precipitated. Storage of waste under saturated conditions that exclude atmospheric CO₂ would therefore provide the optimal environment to minimise V leaching during weathering.

1. Introduction
Steel slag is a ubiquitous byproduct of the steelmaking industry that is produced in large quantities worldwide. It is estimated that 160–240 million tonnes of steel slag were produced in 2016 (Ober, 2017) which corresponds to approximately 10–15% of crude steel output (Piatak et al., 2014). Primary steelmaking (i.e. conversion of iron to steel) produces steel slag via two principal production methods; (1) basic oxygen furnace (BOF) steelmaking in which molten iron from a blast furnace is used and (2) electric arc furnace (EAF) steelmaking which uses a combination of scrap steel, directly reduced iron and pig iron. In both processes lime (or limestone) is added to the furnace as a fluxing agent to remove impurities from the molten metal (Eloneva et al., 2010; Piatak et al., 2014). The composition of BOF and EAF slag is broadly similar and consistent across location and process (Tossavainen et al., 2007; Yildirim and Prezzi, 2011; Proctor et al., 2000). These predominantly consist of Ca, Mg, Fe and Al oxides and silicates (Proctor et al., 2000); the relative proportions of which will vary according to the raw materials used during manufacture. Secondary steelmaking slags are formed during secondary steelmaking where both BOF and EAF derived steels are further processed in ladle furnaces, producing BOF(L) or EAF(L) slags respectively. These are much more variable in composition and are also relatively enriched in Mg and Al due to additives used in the process (Shi, 2002). In addition to slag production, a wide variety of refractories (MgO-C; Al-silicate; MgO-Al₂O₃-C) are used as furnace liners during steelmaking to protect the furnace (Quaranta et al., 2014). Refractories that are in contact with molten slag wear over time and the build-up of solidified slag above the melt (due to sputtering) and in conduits also require regular removal. Therefore, periodic renewal of the entire liner is required. The result is a mixed waste containing both slag and refractories which is difficult to separate and are often co-disposed (Hanagiri et al., 2008).

Primary steelmaking slags are recycled where possible, usually as aggregate in civil engineering applications, such as road construction and as a general fill material due to its stability (Geiseler, 1996;...
leachates (Environment Agency, 2014). Steelmaking wastes at dis-
in steel slags and regulatory concern over high V concentrations in
Comans, 2006; Navarro et al., 2010) due to its relative enrichment
(Chaurand et al., 2006; De Windt et al., 2011; Huijgen and
leaching in particular has received a lot of recent attention
be mobilised in the alkaline leachate (Cornelis et al., 2008). V
et al., 2007; Proctor et al., 2000; Matern et al., 2013) which may
(including Al, Cr, Pb, Mo and V) present in the slag (Tossavainen
A.J. Hobson et al. / Waste Management 81 (2018) 1–10

\[
\begin{align*}
\text{CaO}_2(b) + H_2O &\rightarrow \text{Ca(OH)}_2(s) + 2OH^- & \text{pH}_{(aq)} = 12.46 \\
MgO + H_2O &\rightarrow Mg(OH)_2(s) + 2OH^- & \text{pH}_{(eq)} = 10.40
\end{align*}
\]

Alkalinity may also be produced by the dissolution of Ca-
silicates, (e.g. β-dicalcium silicate, larnite; Roadcap et al. (2005)): 

\[
\text{Ca}_2\text{SiO}_4 + 2H_2O \rightarrow 2\text{Ca}^{2+} + \text{H}_2\text{SiO}_3^{2-} + 2OH^- 
\]

In addition, under aerated conditions, reactions involving the
in-gassing of CO_2 results in conversion of Ca/Mg hydroxide based
alkalinity to carbonate alkalinity.

\[
\begin{align*}
\text{Ca}^{2+}_{(aq)} + \text{CO}_2_{(aq)} + 2OH^-_{(aq)} &\rightarrow \text{CaCO}_3(s) + H_2O(l) \\
\text{CaCO}_3 + H_2O &\rightarrow \text{Ca}^{2+} + \text{HCO}_3^- + OH^- & \text{pH}_{(eq)} = 9.36
\end{align*}
\]

While steel slag has historically been considered to be a non-
hazardous waste, concerns have been raised in recent years regarding
the high concentrations of potential toxic trace metal(loid)s
(including Al, Cr, Pb, Mo and V) present in the slag (Tossavainen
et al., 2007; Proctor et al., 2000; Matern et al., 2013) which may
be mobilised in the alkaline leachate (Cornelis et al., 2008). V
leaching in particular has received a lot of recent attention
(Chaurand et al., 2006; De Windt et al., 2011; Huijgen and
Comans, 2006; Navarro et al., 2010) due to its relative enrichment
in steel slags and regulatory concern over high V concentrations in
leachates (Environment Agency, 2014). Steelmaking wastes at dis-
posal sites are often deposited in both saturated and unsaturated
settings, however, few data currently exist concerning slag lea-
chate generation and chemistry under aerated conditions
(summarised by Cornes et al., 2007). Under aerated conditions, CaCO_3 precipitation
results in a drop in solution pH as OH– ions are consumed (Eq.
(4)). Changes in both pH and redox have significant implications
for the mobility of many potentially toxic metals; for example Al,
Cr, and V mobility and toxicity are all highly dependent on their
speciation (with higher oxidation states generally regarded as
more toxic and mobile) (Pourbaix, 1966).

This study investigates leaching behaviour of co-disposed steel-
making waste under aerated and air-excluded conditions. These
represent contrasting conditions present either near the surface
(good contact with atmosphere) and below the water table deeper
within waste heaps. The waste has been characterised using X-ray
diffraction (XRD) and fluorescence (XRF) techniques, as well as
scanning electron microscopy (SEM) with energy-dispersive X-
ray spectroscopy (EDX) to determine the mineral phases present.
Fully aerated and air-excluded water leaching tests have been per-
formed to determine how phase dissolution behaviour, secondary
mineral formation and trace metal release are affected by changes
in pH and availability of air. Results will assist prediction of metal
release from waste when stored in landfill above and below the
water table, enabling effective environmental risk assessment and
cost-effective long-term management of the waste.

2. Methods and materials

2.1. Sample collection and characterisation

Samples were collected within one week of deposition from the
Yarborough Landfill (British Steel, Scunthorpe, UK) in May 2013
(LAT 53°35′22.24″ LONG 0°35′41.52″). The sample consisted of
50–500 g blocks (~100 kg total). A sub-sample of the collected
material (approx. 500 g consisting of 50 g pieces) were brushed
to remove any fines and crushed to provide a homogenised powder
consisting of ~20–100 μm particles. The crushed waste was stored
in a polythene bag within an airtight glass jar containing soda lime
to prevent weathering due to contact with atmospheric CO_2 and moisture.

Elemental analysis of the powdered waste was undertaken using a PANalytical Axios Advanced X-ray Fluorescence (XRF) spec-
trometer (data corrected for loss on ignition at 1050 °C). Samples
were prepared for major element analysis as fused beads with
lithium metaborate/tetraborate flux (Johnson Matthey Spectroflux
JM100B) (0.6 g sample; 3 g flux). For minor/trace element analysis
pressed pellets were prepared containing ~10 g of dried waste using
~10–20 drops of 6.6% w/v polyvinyl alcohol in a 1:6 mix of
methanol and distilled deionised water as a binder (Moviol 88
solution). The elemental limit of detection (LoD) was generally
<0.02 wt% and the analytical uncertainty (versus certified reference
standards) was <±10% of the data value. Mineralogical analysis
(LoD was approximately 3 wt% for crystalline phases) was under-
taken by powder X-ray diffraction (XRD) using a Bruker D8 diffrac-
tometer, where powder samples were mounted on silicon slides and scanned between 2θ and 70° 2θ using Cu Kα radiation. Diffra-
ction peaks from unknown samples were then matched to known
standard reference patterns using Diffrac.Suite Eva v3.0 software
using the International Centre for Diffraction Data (ICDD) PDF2
database (powder diffraction file (PDF) reference numbers are reported for identified phases).

Two polished blocks were prepared by first cutting waste pieces
to size under water and setting the resultant ~2 cm² blocks into
epoxy resin with the cut surface exposed. This surface was then
polished using a water-free diamond paste to remove the top 1–
2 mm of material potentially exposed to water during cutting.
Electron micrographs were subsequently collected on a FEI
QUANTA 650 FEG ESEM, which was equipped for Oxford Instru-
ments INCA 350 energy-dispersive X-ray spectroscopy (EDS) sys-
tem/80 mm X-Max silicon drift detector. EDS spectra and
elemental maps were collected and analysed using Oxford Instru-
mements Aztec software. The element and sample specific LoD for
EDS analysis was between 0.1 and 0.5 wt%.

2.2. Acid neutralisation capacity (ANC)

Homogenised powdered waste (0.4 g) was mixed with 40 mL
HCl with concentrations ranging from 1 M to 0.001 M in 50 mL
polypropylene Oak Ridge tubes (Nalgene, USA). Experiments were
performed in triplicate. Headspace of the 50 mL tubes were
flushed with N₂ gas prior to sealing. All tubes were subsequently stored in airtight 2 L glass jars (Le Parfait, France) filled with N₂ gas and also containing ~100 g soda lime (as a CO₂ absorbent) to prevent any CO₂ infiltration from atmosphere to the experimental tubes. After 1 and 50 days equilibration the 50 mL tubes were centrifuged in a Sigma 2–16 centrifuge using a 12,151 rotor at 8000 rpm (6000 g) for 5 min to separate aqueous and solid phases. 1 mL of the supernatant was removed and immediately added to 9 mL 0.1 M HNO₃ prior to ICP analysis, and the pH of the remaining solution was measured (pH measurement is described below).

2.3. Leaching tests

Triplicate aerated experiments containing 1 g homogenised powdered waste and 100 mL deionised water were established in open 500 mL PETF Erlenmeyer flasks. These were gently agitated on a Stuart Scientific SSL1 orbital shaker at 175 rpm to allow for equilibrium of the reaction solution with air (i.e. dissolution of atmospheric CO₂ and O₂). At regular intervals over a 50 day period 3 mL aliquots of slurry were removed from the flasks and centrifuged in 2 × 1.5 mL Eppendorf tubes in a Spectraa 16 M microcentrifuge at 14,000 rpm (16,000 g) for 5 min to separate aqueous and solid phases. 1 mL of supernatant was removed and acidified in 0.1 M HNO₃ and the pH of the remaining supernatant was measured (an electrode that was calibrated daily at pH 4, 7 and 10. Nitrogen gas was bubbled through the sample tube during pH measurements made in solutions from the air-excluded experiments to prevent contact with atmosphere. Metal concentrations in acidified aqueous samples from the air-excluded leaching experiments were determined (with an analytical uncertainty of ±3%) using a Thermo iCAP 7400 ICP-OES ion-coupled plasma, optical emission spectrometer (ICP-OES; for Ca, Si, Mg; LoDs were <10 µg L⁻¹) and Thermo iCAP Qc ion-coupled plasma, mass spectrometer (ICP-MS; for V, Mn, and Cr with LoDs <0.1 µg L⁻¹; for Li and Fe with LoD <2 µg L⁻¹). Calibration was against certified multi-element standards and check samples were analysed every 10 samples to check for calibration drift. Aqueous elemental concentrations from the aerated leaching experiments were determined using a Perkin Elmer Optima 5300DV ICP-OES for all elements (LoDs were <100 µg L⁻¹ for all elements). The 5300DV was calibrated with 3 standards (0.1, 1, 10 mg L⁻¹) and a blank which were run every 15 samples and the calibration cross-checked with a trace metal Certified Reference Material (NIST1646A) with all values within ±5%.

2.4. Aqueous analysis

Solution pH (±0.2 pH units) was measured using an Orion DualStar pH/ISE benchtop meter (Thermo Scientific, USA) with an electrode that was calibrated daily at pH 4, 7 and 10. Nitrogen gas was bubbled through the sample tube during pH measurements made in solutions from the air-excluded experiments to prevent contact with atmosphere. Metal concentrations in acidified aqueous samples from the air-excluded leaching experiments were determined (with an analytical uncertainty of ±3%) using a Thermo iCAP 7400 ICP-OES ion-coupled plasma, optical emission spectrometer (ICP-OES; for Ca, Si, Mg; LoDs were <10 µg L⁻¹) and Thermo iCAP Qc ion-coupled plasma, mass spectrometer (ICP-MS; for V, Mn, and Cr with LoDs <0.1 µg L⁻¹; for Li and Fe with LoD <2 µg L⁻¹). Calibration was against certified multi-element standards and check samples were analysed every 10 samples to check for calibration drift. Aqueous elemental concentrations from the aerated leaching experiments were determined using a Perkin Elmer Optima 5300DV ICP-OES for all elements (LoDs were <100 µg L⁻¹ for all elements). The 5300DV was calibrated with 3 standards (0.1, 1, 10 mg L⁻¹) and a blank which were run every 15 samples and the calibration cross-checked with a trace metal Certified Reference Material (NIST1646A) with all values within ±5%.

3. Results

3.1. Material characterisation

The elemental composition (Table 1) of the powder sample was dominated by Ca, Fe, Mg, Si and Al with Cr and Mn as minor constituents. Trace elements included P, V, K, Ti and S.

### Table 1

| Chemical composition of BOF steel slag samples from the Yarborough Repository, Scunthorpe UK, and the powder sample used in leaching tests. |
|------------------------------|
| Major Elements               | BOF slag (Hobson et al., 2017) | Powder sample (this study) |
| Nominal Oxide wt%            |                           |                           |
| CaO                         | 40 ± 5                     | 19 ± 2                    |
| FeO                         | 32 ± 9                     | 16 ± 2                    |
| SiO₂                        | 14 ± 3                     | 11 ± 1                    |
| MgO                         | 5.2 ± 1                    | 28.3                      |
| MnO                         | 4.5 ± 1                    | 2.1 ± 0.2                 |
| Al₂O₃                       | 1.2 ± 0.4                  | 18 ± 2                    |
| F₂O₅                        | 1.3 ± 0.4                  | 0.87 ± 0.09               |
| V₂O₅                        | 0.81 ± 0.24                | 0.33 ± 0.03               |
| TiO₂                        | 0.30 ± 0.13                | 0.86 ± 0.09               |
| Cr₂O₃                       | 0.24 ± 0.13                | 3.3 ± 0.3                 |
| SO₃                         | 0.23 ± 0.09                | 0.33 ± 0.03               |
| K₂O                         | n.d.                       | 0.12 ± 0.01               |
| Na₂O                        | n.d.                       | 0.18 ± 0.02               |
| SiO₂                        | n.d.                       | 0.14 ± 0.01               |
| ZrO₂                        | 0.02 ± 0.01                | 0.14 ± 0.01               |
| BaO                         | n.d.                       | 0.01 ± 0.01               |
| NiO                         | 0.02 ± 0.01                | n.d.                      |
| CuO                         | 0.01 ± 0.01                | n.d.                      |
| ZnO                         | n.d.                       | 0.02 ± 0.01               |
| PbO                         | n.d.                       | 0.03 ± 0.01               |
| LOI                         | 0.96                       |                           |
| TOTAL                       | 98.9                       | 100.9                     |

Mineralogical analysis of the crushed waste using XRD (Fig. 1a) identified the presence of periclase (MgO; PDF #44-946), corundum (Al₂O₃; PDF #10-173), larnite (dicalcium silicate, β-Ca₂SiO₄; PDF #33-302), brownmillerite (dicalcium aluminoferite, Ca₂(Al, Fe)₂O₆; PDF #30-226), wüstite (FeO; PDF #46-1312), brucite (Mg(OH)₂; PDF #44-1482) and elemental carbon (graphite-C; PDF #23-64). The principal XRD peak of free lime (CaO; PDF #37-1497) overlaps with a secondary peak of corundum at ~37.5° 2θ, however, the secondary peaks at ~32 and 54° 2θ were present, suggesting its presence. There was no calcite peaks in the XRD pattern for the unreacted waste (n.b. the principle calcite peak is at ~29° 2θ).

SEM analysis of a polished block (Fig. 2) showed a material that was composed of intergrown 10–30 µm crystallites, EDS elemental mapping indicated that there were three dominant compositions. The dominant composition by area (~65% of the sample viewed) was a Ca-Si-O rich phase containing trace amounts of Al, P, Ti and Mn, corresponding to the larnite phase identified by XRD. The second most abundant composition by area (~25%) was a Mg-Fe-O rich phase containing trace amounts of Na, Ca, Cr and Mn, corresponding to the wüstite phase identified by XRD. The third most abundant composition by area (~10%) was a Ca-Fe-Al-O rich phase containing trace amounts of Ti, V, Cr and Mn, corresponding to the brownmillerite phase identified by XRD. Regions of the dicalcium silicate phase contain lamellae identified as CaO rich regions associated with dicalcium silicate. The second polished block was composed of a single Al-Si-O rich composition containing no significant trace elements (data not shown).

3.2. Acid neutralisation tests

For crushed waste, the relationship between the final solution pH value and the amount of acid added was similar after 1 day and 50 days of equilibration (Fig. 3a). The acid neutralisation capacity (to pH 7) was very similar at the two time-points (11.0 and 9.5 M H⁺ kg⁻¹ waste, respectively). In tests where the final pH value was >7, the pH value increased with time. The solution Ca and Mg concentrations at a particular pH value were broadly similar after 1 day and 50 days (Fig. 3c, d), however, Si (Fig. 3b) was present in solution at all final pH values <10 after 1 day, but
was present at significantly reduced concentrations at 50 days at all pH values. Calcium was released to solution at all pH values, with generally higher concentrations at lower pH values. Magnesium was only present in solution below \( \text{pH} 10 \), but also has generally higher concentrations at lower pH values.

### 3.3. Batch leaching tests

During air-excluded leaching (Fig. 4), the leachate pH rose rapidly within the first hour to a value of 11.4, and then increased more slowly to a maximum value of 11.9 after 52 days. The Ca
concentration increased rapidly to \( \sim 2.5 \text{ mmol L}^{-1} \) over the first 24 h, and then more steadily to \( \sim 3.0 \text{ mmol L}^{-1} \) after 5 days. Between 5 days and 10 days the Ca concentration decreased to \( \sim 2.5 \text{ mmol L}^{-1} \), but thereafter increased steadily to \( \sim 3.4 \text{ mmol L}^{-1} \) after 50 days. The Mg concentration showed no trend with time and was \(<0.4 \text{ mmol L}^{-1} \) throughout the experiment. The Si concentration increased to \( \sim 0.15 \text{ mmol L}^{-1} \) over the first 24 h, and then to \( \sim 0.25 \text{ mmol L}^{-1} \) after 5 days. After about 10 days the Si concentration decreased to \( \sim 0.15 \text{ mmol L}^{-1} \) but subsequently varied between \( \sim 0.15 \) and \( \sim 0.25 \text{ mmol L}^{-1} \) until the end of the test. The V concentration gradually increased from \( \sim 0.002 \text{ mmol L}^{-1} \) after 24 h to \( \sim 0.007 \text{ mmol L}^{-1} \) after 50 days. Aqueous Fe concentrations range from 0.002 to 0.07 mmol L\(^{-1}\) and were just above the limit of detection by ICP-MS (0.0018 mmol L\(^{-1}\)), which increases scatter in the data. However, it is still discernible that Fe accumulated in solution during the air-excluded experiments and did not in parallel aerated experiments. There was very little change in XRD patterns collected from the solid residue over time, except that portlandite (PDF #44-1481) was detected in samples collected from the experiment end points (Fig. 1b).

During the aerated experiments (Fig. 4), pH increased rapidly within the first hour to a maximum value of 11.6. This was followed by a decrease to pH 8.9 after 1 day and then by a second rise to pH 10.0 after 6 days. Subsequently pH steadily declined to 9.3 after 50 days of leaching. The Ca concentration increased rapidly to \( \sim 2 \text{ mmol L}^{-1} \) within the first two hours, but then decreased to \( \sim 0.25 \text{ mmol L}^{-1} \) after 6–7 days. Initially the Mg concentration was low but it increased rapidly after day 2 to reach a concentration above 12.5 mmol L\(^{-1}\) by day 20, which persisted until the end of the test. The Si concentration was \( \sim 0.15 \text{ mmol L}^{-1} \) after 1 h, decreased to \( \sim 0.03 \text{ mmol L}^{-1} \) after 2 days but then rose to \( \sim 0.25 \text{ mmol L}^{-1} \) at 6 days. Subsequently Si concentrations remained above 0.2 mmol L\(^{-1}\) for the remainder of the test. The V concentration increased steadily over the duration of the test to reach a maximum of \( \sim 0.065 \text{ mmol L}^{-1} \) after 48 days. The aqueous Fe concentrations were initially around 0.05 mmol L\(^{-1}\) and decreased over 5 days to \(<0.002 \text{ mmol L}^{-1}\) for the remainder of the tests. XRD patterns collected from solid residue after 1 day show that calcite (PDF #24-27) was present (Fig. 1c), after 6 days the periclase and larnite peaks had reduced in relative intensity and monohydrocalcite (PDF #29-306) was detected (Fig. 1d). After 50 days monohydrocalcite was the dominant secondary phase detected (although some dolomite, PDF #36-426, was also present) and periclase and larnite peaks were absent (Fig. 1e).

Concentrations of other trace elements considered to be potential environmental risk drivers for steel slags (e.g. Mn, Cr, Li) were low in both the aerated and the air-excluded tests (and were present at concentrations close to or below the limit of detection).

4. Discussion

4.1. Waste characterisation

The bulk chemical and mineralogical composition of the waste was distinct from BOF slag samples collected at the Yarborough site (Table 1). Compared to BOF slag the material was relatively depleted in elements such as Ca, Fe, Mn and V; but enriched in Mg, Al, Ti and Cr. The waste mineralogy could be split into two distinct groups. The first group included a range of phases commonly occurring in BOF slag (i.e. larnite, brownmillerite, lime, and wüsite; Yildirim and Prezzi, 2011; Proctor et al., 2000; Geiseler, 1996), which were observed in SEM as discrete particle assemblages within an intergrown matrix of 20–50 μm crystallites. The
second group of minerals identified by XRD included corundum, periclase and graphite that are rare in BOF slag and are more commonly associated with refractory liner materials (e.g. in MgO-C and Al₂O₃-MgO-C refractories; Rovnushkin et al., 2005). Aluminosilicate was also observed in SEM analysis. This was most likely the high temperature phase mullite (Al₂Si₂O₇; Schneider et al., 1994; Chesters, 1973; Mazdiyasni and Brown, 1972; Tamari et al., 1993) which is also used as a refractory material or can form in slags from reaction of corundum and Si (Dana and Das, 2004; Zhao et al., 2014). Therefore, the waste can be characterised as a mixed steelmaking waste containing both BOF slag and refractory materials. The potential for re-use of mixed wastes is low due to uncertainties about their chemical and physical behaviour, however, it is important to understand their potential leaching behaviour during disposal.

4.2. Acid neutralisation behaviour

The acid neutralisation capacity experiments were conducted under air-excluded conditions and provide information on phase dissolution in the waste as a function of the acid addition and final solution pH. At low acid additions (<1 mol H⁺ kg⁻¹) the waste buffered pH to values >11.5 due to the dissolution of free lime and dicalcium silicate (Eqs. (1) and (3)), with dissolution of brucite from periclase hydration also consuming acid when the pH < 10.4 (Eq. (2)). Ca was released to solution at all pH values with the amount of release increasing with decreasing pH (Fig. 3c), and Mg was released to solution when pH values <10 with the amount of release also increasing with decreasing pH (Fig. 3d), which is consistent with the dissolution behaviour of these phases (Eqs. (1) and (2)). The alkalinity producing phases were progressively exhausted by larger acid additions and the final pH decreased steadily until neutral values were reached with an acid addition of ~8 mol H⁺ kg⁻¹. CaO hydration is a very fast reaction (Shi et al., 2002), whereas dicalcium silicate hydration and dissolution is generally considered to be slower (Taylor, 1986). However, here we find that both are involved in buffering the pH in the first 24 h as Si is released to solution. Nevertheless, the 10:1 ratio in the aqueous Ca and Si concentrations indicated an excess of Ca release relative to pure dicalcium silicate dissolution (i.e. Ca:Si ≈ 2:1) suggesting that free lime was the dominant Ca bearing phase that was dissolving over 24 h.

The difference in the final pH of the 1 and 50 day tests with the same acid addition indicates that part of the alkalinity generation occurs over longer time periods. At high pH this was most likely associated with continued dissolution of dicalcium silicate, although the Si concentrations decreased between day 1 and 50. This Si decrease was most likely associated with the formation of secondary Si-containing phases. These phases were most probably calcium-silicate-hydrate (Ca-Si-H) phases at pH values >9 (Walker et al., 2016; Costa et al., 2016) and amorphous silica (SiO₂ (am)) at lower pH values (Langmuir, 1997). The increase in Mg concentration between day 1 and 50 at pH values <9 suggests periclase hydration also continued beyond 24 h.

4.3. Leaching behaviour under aerated conditions

At the initial sampling point (1 h) during the aerated leaching tests, the pH value was 11.5 ± 0.2 and both Ca and Si were released to solution. This rapid initial release of alkalinity, Ca and Si was due

![Fig. 3. Acid neutralisation results showing (a) final pH values after 24 h (red circles) and 50 days (black squares) as a function of initial acid concentration (each point represents the mean value and error bars ±1 r from triplicate samples) and (b–d) metal concentrations leached from waste over 24 h and 50 days as a function of final pH. Initial test conditions in all cases were 10 g waste L⁻¹. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)](image-url)
to the hydration and dissolution of both free lime and dicalcium silicate phases present in the waste. Previous slag leaching tests using granulated BOF slag pieces found dicalcium silicate dissolution to be significantly slower than free lime dissolution (Stewart et al., 2018). The use of crushed powder samples in these tests which will have contained high surface area fines must have promoted rapid initial dissolution of dicalcium silicate. However, as dicalcium silicate dissolution releases Ca and Si to solution in an approximately 2:1 ratio (Hobson et al., 2017), the much higher initial Ca/Si ratios in solution (between 13 and 20) indicates that free lime dissolution was most likely to be the predominant source of rapidly leached alkalinity in these tests.

In the 2 days after the initial release of alkalinity Ca and Si to solution, the pH reduced to 8.9 contemporaneously with rapid Ca and Si removal. The decrease in pH and Ca concentrations coincides with the appearance of calcite peaks in the XRD plots after 1 h (Fig. 1) indicating that the initial spike in pH was buffered down to 8.9 due to in-gassing of atmospheric CO$_2$ and the subsequent precipitation of CaCO$_3$, which consumes both OH$^-$ and Ca$^{2+}$ ions (Eq. (4)). The contemporaneous decrease in Si concentrations may be evidence of the formation of a calcium silicate hydrate phase (Ca-Si-H). Indeed, low Ca/Si ratio (<1) Ca-Si-H phases are predicted to form under the observed initial pH and Ca concentrations on a timescale of 24–48 h (Walker et al., 2016). The peaks associated with dicalcium silicate (larnite) in XRD patterns became less prominent over time and were ultimately absent by the end of the experiments, indicating continued dicalcium silicate dissolution beyond day 6. Despite this no further increase in Ca concentra-
Ca-Si-H gel formation can cover particle surfaces, making alkalinity generation a diffusion-limited process (Hobson et al., 2011; Costa et al., 2016; Nikolić et al., 2016), slowing the dissolution of the remaining reactive solid phases, and leading to the incomplete dissolution of larnite (dicalcium silicate) observed at the end of these experiments (Fig. 1b). No Mg was released to solution under air-excluded conditions because the pH remained above 10.4 throughout the experiments, and therefore, dissolution of the Mg containing phases was inhibited.

4.5. Control of trace metal release

Fe can be released to solution during dissolution of both free lime and dicalcium silicate (in which it can be a minor constituent; Hobson et al., 2017), and therefore Fe is present in the leachate throughout the air-excluded experiments (The slightly lower Fe concentrations after 5 days under air-excluded conditions may be due in part to incorporation of some Fe into Ca-Si-H phases). Conversely, under aerated conditions Fe is only present in significant concentrations during the first 3 days during which time the leachate pH falls from 11.5 to 9. Under aerated conditions, any Fe(II) released is likely to be readily oxidised to Fe(III) and precipitated either as an insoluble hydroxide or incorporated into spinel-like secondary phases (e.g. magnetite, Fe₃O₄; De Windt et al., 2011)) at pH 9, limiting Fe accumulation in solution.

Vanadium release in the air-excluded experiments is low (maximum of ~0.007 mmol L⁻¹) compared to that observed in the aerated experiments (maximum of ~0.065 mmol L⁻¹). Previous work on BOF slag weathering suggests that it is V(V) associated with dicalcium silicate which is most readily leached to solution (Hobson et al., 2017), which is present in high pH solution as the vanadate oxyanion (VO₄³⁻; Wehrli and Stumm, 1989). Thus, V concentrations observed during BOF slag leaching are likely to be controlled by Ca₃(VO₄)₂ solubility limits (Ksp = 1.0 × 10⁻³⁸; Huijgen and Comans, 2006; Cornelis et al., 2008; Allison et al., 1991) which impose an inverse relationship between Ca and V concentrations in the leachate (Fig. 5).

\[
3Ca^{2+} + 2VO_4^{3-} \rightleftharpoons Ca_3(VO_4)_2
\] (6)

4.4. Leaching behaviour under air-excluded conditions

At the first sampling point at 1 hr the pH value and the Ca and Si concentrations were very similar to those observed in the aerated experiments (pH 11.5 ± 0.2, [Ca] 1.5 ± 0.5 mmol L⁻¹ and [Si] 0.15 ± 0.025 mmol L⁻¹) indicating similar processes were occurring over the first hour of leaching in both experiments (i.e. rapid dissolution of free lime and fine grained dicalcium silicate particles). As a saturated Ca(OH)₂ solution will reach a pH of ~12.5 (Eq. (1)) and experimental pH values were between 11 and 12 at all-time points, it suggests that the magnitude of the initial rise in pH was mass limited (i.e. controlled by the amounts of CaO and reactive dicalcium silicate that are readily available for dissolution) rather than Ca(OH)₂ solubility limited. Between the first sampling point and day 5 there was a slow increase in pH, Ca and Si which was probably the result of continued dicalcium silicate dissolution.

Between day 5 and 10 in the air-excluded experiments there was a decrease in Ca concentrations that coincided with a decrease in Si concentrations, which suggests that a Ca-Si-H phase formed. The pH, Ca and Si concentrations present at the time of formation in the leaching experiments were consistent with precipitation of a Ca-Si-H phase with Ca/Si ratio of close to 1 (Walker et al., 2016). The continuing slow rise in pH, Ca and Si concentrations during the remainder of the experiment indicate that under air-excluded conditions, the solution composition slowly evolves towards dicalcium silicate solubility limits over time (also observed by De Windt et al., 2011). However, Ca-Si-H gel formation can cover particle surfaces, making alkalinity generation a diffusion-limited process (Hobson et al., 2017; Costa et al., 2016; Nikolić et al., 2016), slowing the dissolution of the remaining reactive solid phases, and leading to the incomplete dissolution of larnite (dicalcium silicate) observed at the end of these experiments (Fig. 1b). No Mg was released to solution under air-excluded conditions because the pH remained above 10.4 throughout the experiments, and therefore, dissolution of the Mg containing phases was inhibited.

4.5. Control of trace metal release

Fe can be released to solution during dissolution of both free lime and dicalcium silicate (in which it can be a minor constituent; Hobson et al., 2017), and therefore Fe is present in the leachate throughout the air-excluded experiments (The slightly lower Fe concentrations after 5 days under air-excluded conditions may be due in part to incorporation of some Fe into Ca-Si-H phases). Conversely, under aerated conditions Fe is only present in significant concentrations during the first 3 days during which time the leachate pH falls from 11.5 to 9. Under aerated conditions, any Fe(II) released is likely to be readily oxidised to Fe(III) and precipitated either as an insoluble hydroxide or incorporated into spinel-like secondary phases (e.g. magnetite, Fe₃O₄; De Windt et al., 2011)) at pH 9, limiting Fe accumulation in solution.

Vanadium release in the air-excluded experiments is low (maximum of ~0.007 mmol L⁻¹) compared to that observed in the aerated experiments (maximum of ~0.065 mmol L⁻¹). Previous work on BOF slag weathering suggests that it is V(V) associated with dicalcium silicate which is most readily leached to solution (Hobson et al., 2017), which is present in high pH solution as the vanadate oxyanion (VO₄³⁻; Wehrli and Stumm, 1989). Thus, V concentrations observed during BOF slag leaching are likely to be controlled by Ca₃(VO₄)₂ solubility limits (Ksp = 1.0 × 10⁻³⁸; Huijgen and Comans, 2006; Cornelis et al., 2008; Allison et al., 1991) which impose an inverse relationship between Ca and V concentrations in the leachate (Fig. 5).

\[
3Ca^{2+} + 2VO_4^{3-} \rightleftharpoons Ca_3(VO_4)_2
\] (6)
Under air-excluded conditions Ca released from CaO and dicalcium silicate weathering occurred in solution, producing a leachate with high Ca concentrations. The leachate solution, therefore, quickly reached Ca\(_3(VO_4)_2\) solubility limits, preventing further release of V to solution and limiting V concentrations in the leachate.

Aerated conditions, however, allow in-gassing of atmospheric CO\(_2\) and associated formation of secondary carbonate minerals. This process provides a sink for Ca, lowering aqueous Ca concentrations. The V that is released therefore persists in solution (due to the lower \([Ca^{2+}]/[VO_4^{3-}]\) ion activity product), leading to much higher concentrations than those seen under air-excluded conditions. Monohydrocalcite is relatively soluble (K\(_{sp}\) = \(1 \times 10^{-7.2}\); Kralj and Brečević, 1995), therefore, the equilibrium phase controlling Ca concentrations in these experiments is probably dolomite (CaMg(CO\(_3\))\(_2\); K\(_{sp}\) = \(1 \times 10^{-17.2}\); Sherman and Barak, 2000). Indeed, the predicted Ca concentration in solutions equilibrated with dolomite and atmospheric pCO\(_2\) are similar to those found at the end of these experiments (Fig. S; Langmuir, 1997). In the aerated experiments, the overall leachate chemistry remains undersaturated with respect to Ca\(_3(VO_4)_2\), which is consistent with the observed depletion of the V-hosting dicalcium silicate phase by the end of the aerated experiments.

4.6. Implications for waste management

Co-disposed wastes such as those used in this study are unattractive for reuse in furnaces due to their highly variable composition making it difficult to control the steelmaking processes. Furthermore, the presence of MgO makes their reuse in civil engineering applications difficult, since periclase hydration to form brucite leads to significant volumetric expansion and cracking. Given these problematic characteristics, combined steelmaking wastes are generally stored in landfill. Over time, rainwater inevitably infiltrates and reacts with landfilled waste to generate leachate. Therefore, the storage environment plays a key role in establishing leachate composition. There is a key interaction between Ca concentrations and the solution pH, which controlled by the equilibrium with the dominant Ca-phase present (i.e. portlandite, Ca-Si-H or CaCO\(_3\)). The presence of CO\(_2\) is a key factor in determining which secondary Ca phases are present during leaching and also the degree to which the primary dicalcium silicate was leached (therefore, indirectly affecting the release of trace metals such as V).

Under air-excluded conditions, the leaching profile of the combined waste is similar to that of BOF slag (Hobson et al., 2017; De Windt et al., 2011; Huijgen and Comans, 2006; Costa et al., 2016). Rapid dissolution of Ca-bearing phases without in-gassing of CO\(_2\) leads to a high pH, Ca(OH)\(_2\) dominated leachate. High Ca concentrations limit V release due to Ca\(_3(VO_4)_2\) solubility limits. Consequently, water saturated environments with limited opportunity for CO\(_2\) ingress will provide the safest environment for waste storage. Leachate could either be recirculated (and reach equilibrium with Ca(OH)\(_2\)) or be removed and treated off site to lower its pH and allow carbonation without triggering V release (Gomes et al., 2017). Under aerated conditions, lower alkalinity and Ca concentrations allow much higher V concentrations to accumulate in leachate, as well as allowing dissolution of MgO to form a Mg(OH)\(_2\) dominated leachate which favours the formation of monohydrocalcite and dolomite as secondary carbonate phases. Leaching under aerated conditions rapidly produces leachate with V concentrations in excess of acute toxicity thresholds (280 µg L\(^{-1}\); Fig. 5) and all experiments display V concentrations higher than chronic toxicity thresholds (19 µg L\(^{-1}\); Buchman, 2008). New proposals for V exposure based on recent reviews of ecotoxicology data (Smit, 2012) have suggested new water quality standards for V of 1.2 and 3.0 µg L\(^{-1}\) for chronic and acute exposure respectively. Almost all slag leachates reported (Fig. 5) would exceed these more stringent limits, therefore, leachate generated from co-disposed steel making wastes would require careful management (and treatment prior to discharge) to avoid the potential for environmental harm.

Extrapolating from experimental results to field scale predictions must always be done with caution. For example, these experiments were performed on crushed powder samples at much lower solid to liquid ratios than would typically be found in a heap leaching scenario. It is much more likely that during heap leaching (due to high solid:solution ratios present) free lime and dicalcium silicate dissolution will control leachate quality resulting in higher Ca concentrations (i.e. leachate saturated with respect to Ca(OH)\(_2\)) and therefore lower V concentrations compared to those seen in experimental systems (indeed most real site leachates commonly contain V at order of magnitude lower concentrations than found in laboratory experiments; Fig. 5). However, the experimental results indicate that although carbonation reactions are helpful in reducing pH and alkalinity over time, the lower Ca concentrations produced may allow higher V concentrations to accumulate in leachates over time. Therefore leachates produced from co-disposed steelmaking wastes will likely require monitoring and secondary treatments (e.g. by employing wetlands or cascade systems; Gomes et al., 2017) for decades after their initial disposal.

5. Conclusions

The co-disposed waste investigated in this study was composed of BOF steelmaking slag containing dicalcium silicate, wüstite, dicalcium aluminoferrite and free lime; and refractory oxides comprising corundum, periclase, graphite and high temperature aluminosilicate. V was predominately associated with the dicalcium silicate and dicalcium aluminoferrite phases. During leaching, alkalinity was produced by dissolution of free lime and dicalcium silicate. Under air-excluded conditions high Ca concentrations and the inverse relationship between Ca and V concentrations imposed by Ca\(_3(VO_4)_2\) solubility limits restricted V release to the leachate. Under aerated conditions in-gassing of CO\(_2\) promoted carbonation reactions and secondary carbonate formation. Leachate pH and Ca concentrations were reduced and MgO hydration and dissolution was promoted leading to a switch from a Ca to an Mg dominated leachate and precipitation of monohydrocalcite and dolomite. V concentrations in leachate were higher under aerated conditions where formation of carbonate minerals provides a sink for aqueous Ca following in-gassing of CO\(_2\). Under these conditions, the inverse relationship imposed by Ca\(_3(VO_4)_2\) solubility limits allows higher concentrations of V to accumulate in leachate than those seen under air-excluded conditions. Therefore, when considering long-term leaching behaviour, it is important that risk assessments consider the expected in situ environmental chemistry of specific waste storage environments.

Acknowledgements

This research was funded by a UK Natural Environment Research Council PhD studentship to AJH and UK NERC grants NE/L014055/1 and NE/L014211/1 under the Resource Recovery from Waste theme. We thank Andy Connelly, Lesley Neve, Stephen Reid, Richard Walshaw and Duncan Hedges (all University of Leeds) for lab assistance, XRD, ICP-OES/MS and SEM analysis respectively. We also thank Nick Marsh at the University of Leicesters and Bob Knight at the University of Hull for XRF and additional ICP-OES respectively.
