The reversibility metal-insulator transition in VO$_2$ at $T_C \approx 340$ K has been closely scrutinized yet its thermodynamic origin remains ambiguous. We discuss the origin of the transition entropy by calculating the electron and phonon contributions at $T_C$ using density functional theory. The vibration frequencies are obtained from harmonic phonon calculations, with the soft modes that are imaginary at zero temperature renormalized to real values at $T_C$ using experimental information from diffuse x-ray scattering at high-symmetry wavevectors. Gaussian Process Regression is used to infer the transformed frequencies for wavevectors across the whole Brillouin zone, and in turn compute the finite temperature phonon partition function to predict transition thermodynamics. Using this method we predict the phase transition in VO$_2$ is driven five to one by phonon entropy over electronic entropy.

Keywords: metal-insulator transition, thermodynamics, phonon entropy, VO$_2$, Gaussian Process Regression

The first-order phase transition in VO$_2$ occurs at a temperature of $T_C \approx 340$ K, and is coupled to defect concentration, strain field, electric field and optical fluence. The transition has been studied since Klemm and Grimm in the 1930’s, Cook in the 40’s, and in detail by Morin in 1959. Fundamental questions on the nature of the transition have been debated for decades and continue to be researched. The transition occurs most notably in temperature so understanding the thermodynamic origin is a point of basic importance.

In this study we use density functional theory (DFT) to predict the origin of the VO$_2$ transition entropy. The applicability of DFT to describe the transition metal oxide class of solids depends sensitively on technical details. We use non-spin-polarized calculations based on the PBE exchange correlation functional with on-site Coulomb correction $U_{eff} = 3$ eV. As shown in Fig. 1, this approach leads to agreement with experiment on the following important points:

1. Electronic structure – the high-symmetry metallic R phase is appropriately gapless. Band gap is opened smoothly with V-V dimerization, resulting in a semiconducting monoclinic (M1) phase.

2. Transition enthalpy – the low-temperature M1 phase is energetically favored over the high-temperature R phase.

3. Mechanical stability – the low-symmetry M1 phase is stable against distortion and the high-symmetry R phase is unstable in 0 K DFT simulation.

Including spin polarization is shown in Fig. 1 to lower the DFT energy of R-VO$_2$ with respect to the non-magnetic solution, destroying agreement with experiment for the points listed above. The problems related with spin polarization in the DFT description of VO$_2$ have been discussed before, and have been resolved fully only in the context of Quantum Monte Carlo simulations, which are too computationally expensive to use to investigate lattice dynamics. We therefore take the pragmatic approach employed by other authors of using non-magnetic calculations on the basis on agreement with experiment.

For the M1 phase, the Born-Oppenheimer surface is convex about equilibrium coordinates. The harmonic approximation to the interatomic potential is appropriate for small displacements, and is expected to be adequate for M1-VO$_2$ up to $T_C$. On the other hand the high-symmetry R phase has negative second-order force constants which qualitatively invalidate free energy predictions at the harmonic level. Approaches to remedy this include anharmonic effects have become more accessible thanks to recent developments, enabling the description of systems with light atoms, at ultra-high temperatures, or near phase transitions, yet widespread application of first principles anharmonic thermodynamics remains limited due to computational cost and complexity. In this work we present a simple, experimentally-motivated approach to compute the thermodynamics of temperature-stabilized imaginary modes in VO$_2$. The method is low-cost and applicable generally to the DFT thermodynamics of high-temperature phases that are unstable at zero temperature.

In the soft mode theory of Cochran and in Landau phenomenological approaches, a square-root temperature dependence is identified for transition parameters. The squared-frequency $\tilde{\omega}_i^2$ of a mode $i$ that softens near the transition at wavevector $\mathbf{q}$ is expected to decrease lin-
Figure 1. Potential energy surface (eV/\(\text{VO}_2\)) and band gap (eV) as a function of dimerization \(\delta\) (Å), which is the difference in \(d(\text{V-V})\) between consecutive pairs of cations along the rutile c axis. Values are shown for non-magnetic (NM), antiferromagnetic (AFM) and ferromagnetic (FM) ordering, and for a range of \(d\) electron on-site Coulomb interaction strengths, \(U_{\text{eff}} = [0,3]\) eV. The NM \(U_{\text{eff}} = 3\) eV description appropriately opens the band gap in dimerization and provides a mechanically unstable high-symmetry phase.

early with temperature towards a first-order solid-state transition:

\[
\tilde{\omega}_i^{2\text{R}}(T) \propto T - T_0.
\]  

In \(\text{VO}_2\) this proportionality has been observed in experimental measurements. For example, Cohen and Terauchi report a linear temperature response from diffuse x-ray scattering measurements at \(q = \text{R} \) with \(R = \left(\frac{1}{2},\frac{1}{2}\right)\) which is represented in the left axis in Fig. 2. The temperature \(T_0\), when \(\tilde{\omega}_{i\text{R}} \to 0\), has a value of \(T_0 = 329\) K, and corresponds to the classical second-order transition temperature. Along with the first-order transition temperature \(T_C\), Eqn. 1 relates the phonon frequency at 0 K, \(\omega_{i\text{R}}^{2\text{R}}(0)\), to the frequency at the transition temperature as

\[
\hat{\omega}_{i\text{R}}^{2\text{R}}(T_C) = \omega_{i\text{R}}^{2\text{R}}(0) \frac{T_C - T_0}{T_0}.
\]

Here the shifted frequency \(\hat{\omega}_{i\text{R}}(0)\) is equal to the harmonic frequency \(\omega_{i\text{R}}\) that is calculated with DFT. The application of the transformation of imaginary harmonic DFT frequencies at 0 K to real frequencies at \(T_C\) is shown in Fig. 2. The method gives values for the temperature-stabilised frequencies at negligible additional cost to standard harmonic DFT calculations, provided the coefficients \(T_0\) and \(T_C\) are known, which is commonly the case as shown by the experimental data reviewed by Cochran and Cowley.

To implement the frequency shifts for R-\(\text{VO}_2\), the transition modes which are shown in Fig. 2 to be imaginary at \(\text{R, Z and A in } q_z = \frac{1}{2}\) are renormalized to \(T_C\) following the prescription described in the previous paragraph. At other R-\(\text{VO}_2\) wavevectors (see Brillouin zone geometry, Fig. 3 Appendix), the frequencies do not soften to imaginary harmonic frequencies. For example, in Fig. 2 the \(\Gamma, X,\) and \(M\) wavevectors in \(q_z = 0\) have real harmonic frequencies at \(T = 0\) K. The frequencies in \(q_z = 0\) that do not soften are modelled using the DFT harmonic frequencies \(\omega_{i\text{q}}\).

In order to make thermodynamic predictions for a high-temperature phase we need to sample the transformed modes finely across the Brillouin zone, not only at the limited high-symmetry \(q\)-points in the \(q_z = \frac{1}{2}\) and \(q_z = 0\) regions described. To obtain \(\hat{\omega}_{i\text{q}}(T_C) \in \mathbb{R}^{\forall i\text{q}}\), the partial knowledge we already have of the frequencies transformed to \(T_C\) is found to be sufficient data for machine learning techniques to interpolate \(\hat{\omega}_{i\text{q}}(T_C)\) to arbitrary phonon wavevectors. \(\hat{\omega}_{i\text{q}}(T_C)\) is inferred at all irreducible Brillouin zone wavevectors using Gaussian Process Regression (GPR), enabling the partition function of the R-\(\text{VO}_2\) vibrational system to be specified at \(T_C\). GPR accuracy benchmarks and technical details are provided in Appendix IV.
To understand the source of entropy driving the transition, we compute \( S_{\text{DFT}} = S_R - S_{M1} \) at \( T_C \). \( S_{M1} \) is the DFT harmonic vibrational entropy of M1-VO₂, and for R-VO₂ the entropy is calculated as \( S_R = S_R^\text{el} + S_R^\text{ph} + S_R^\text{spin} \) with consecutive terms from electrons, the harmonic phonon entropy, and the soft-mode phonon entropy from the two experimentally-renormalized transition modes. Thermodynamic calculation details are provided in Appendix III.

The total transition entropy we predict for VO₂ is \( S_{\text{DFT}} = 1.42 \) k\text{B}/V\text{O}_2. The commonly referenced calorimetric value is \( S_{\text{exp}} = 1.5 \) k\text{B}/V\text{O}_2. Our predicted value of \( S_{\text{DFT}} = 1.42 \) k\text{B}/V\text{O}_2 is composed of the contributions \( S_{\text{el}}^\text{el} = 0.25 \) and \( S_{\text{ph}}^\text{ph} = 1.17 \) k\text{B}/V\text{O}_2. The source of entropy driving the transition is therefore phonons over electrons at a ratio of almost five to one. Our entropy predictions are compared to a range of historically reported values presented in Table I. The values range widely, from \( S_{\text{el}}^\text{el} = 0.01 \) to 0.6 k\text{B}/V\text{O}_2 and \( S_{\text{ph}}^\text{ph} = 0.64 \) to 1.35 k\text{B}/V\text{O}_2.

A controversial point that merits discussion is the possibility of a spin contribution to the transition entropy. Quantum Monte Carlo calculations have predicted that the R phase, which in nature only exists above \( T_C \), would be spin ordered at \( T = 0 \) K[50]. On this basis Xia and Chen suggest a spin contribution to the transition entropy. Accounting for a coincident spin disordering at \( T_C \) in our predictions increases the entropy value by \( \ln(2) = 0.69 \) k\text{B}/V\text{O}_2 to \( S_{\text{DFT}} = S_{\text{el}}^\text{el} + S_{\text{ph}}^\text{ph} + S_{\text{spin}} = 0.25 + 1.17 + 0.69 = 2.11 \) k\text{B}/V\text{O}_2, which exceeds the experimental value of \( S_{\text{exp}} = 1.5 \) k\text{B}/V\text{O}_2. If a \( \ln(2) \) spin contribution to the transition entropy exists, \( S_{\text{ph}}^\text{ph} \) must be considerably lower for \( S_{\text{DFT}} \) to remain consistent with \( S_{\text{exp}} \). Considering the neutron scattering measurements by Budai et al. we are inclined to believe this is unlikely. The neutron measured phonon density of states (DOS) can be used to estimate a phonon entropy of 1.32 k\text{B}/V\text{O}_2 (Table I), which is even larger than our predicted value of \( S_{\text{ph}}^\text{ph} = 1.17 \) k\text{B}/V\text{O}_2, rather than smaller as required to accommodate a spin term. We therefore consider that a fully disordered Heisenberg spin contribution to the transition unlikely. In order to confirm or refute inferences...
based on our experimentally-renormalized DFT thermodynamics and the neutron scattering measurements of Budai et al.\textsuperscript{[33]} we propose a simple experiment to measure $T_C$ in the presence of a strong magnetic field. If there is a spin contribution to the entropy, it should vanish in the presence of the magnetic field, which will bring the value of $T_C$ significantly up. If there is no magnetic entropy involved in the transition, $T_C$ should not change or change very little in the presence of the field.

CONCLUSION

We have described the source of entropy driving the VO$_2$ metal-insulator transition. Our thermodynamic predictions suggest the transition is driven by phonons over electrons at a ratio of 1.17 : 0.25. In order to make our predictions we have performed DFT harmonic phonon calculations, in conjunction with an experimentally-motivated soft-mode renormalization scheme based on data from x-ray scattering measurements. The scheme has predicted values of soft-mode frequencies at the transition temperature for high-symmetry points in the Brillouin zone of R-VO$_2$. The machine learning interpolation method Gaussian Process Regression was used to infer the soft-mode frequencies across the full Brillouin zone based on the input of frequencies at partial high-symmetry wavevectors. A simple procedure has been proposed to experimentally confirm or refute claims of a spin disorder contribution to the transition entropy.

Appendix

I. DFT CALCULATIONS

Periodic DFT calculations were performed with the Vienna Ab-initio Simulation Package (VASP) [51,52] using the generalized gradient approximation (GGA) in the form of the Perdew-Burke-Ernzerhof exchange-correlation functional (PBE) [23]. The projected augmented wave method was used to describe the interaction between the valence electrons and the core states, which were kept frozen at the atomic references (up to 3p in V and 1s in O) [53]. Plane waves were cutoff at a kinetic energy of 520 eV, and k-points were sampled at a density of 6 × 6 × 9 divisions per rutile unit cell. Force and energy convergence thresholds were set to 10^{-3} eV/Å and 10^{-6} eV respectively.

The Coulomb interaction between vanadium d electrons was corrected with an effective on-site term, \(U_{\text{eff}}\) [54]. The effect of \(U_{\text{eff}}\) and magnetic ordering was considered for phase enthalpy and band gap. The interplay of \(U_{\text{eff}}\) and magnetic ordering with dimerization is shown in Fig. [1]. NM \(U_{\text{eff}} = 3\) eV calculations reproduce the basic characteristics well known from experiment, including instability of the high-symmetry \(P4_2/mnm\) rutile phase at low temperature, and electronic band gap phase opening with V-V dimerization.

II. PHONON CALCULATIONS

Phonons were computed from second-order force constants using the PHONOPY code [55]. The M1 and R phases employ \(2 \times 2 \times 2\) and \(2 \times 2 \times 3\) supercells respectively. Phonon thermodynamics functions were satisfactorily converged at a sampling density equivalent to \(16 \times 16 \times 24\) q-point mesh for the rutile conventional unit cell.

Harmonic DFT phonon dispersion is shown in Fig. [3]. The Brillouin zones for M1 and R unit cells are sampled between high symmetry points in reciprocal space. The path for R-VO2 follows the sequence \{\(Z, \Gamma, M, A, Z, R, X, \Gamma\}\) which corresponds to \{\(00\frac{1}{2}, 000, \frac{1}{2} \frac{1}{2} 0, \frac{1}{2} \frac{1}{2} \frac{1}{2}, 00\frac{1}{2}, \frac{1}{2} \frac{1}{2} \frac{1}{2}, \frac{1}{2} \frac{1}{2} 0, 000\}\}. The path for M1-VO2 is \{\(\Gamma, C, Z, \Gamma, B, D, Z, \Gamma, A, E\)\} which corresponds to \{00, 0\(\frac{1}{2}\)0, \(\frac{1}{2}\)0, \(\frac{1}{2}\)0, 00, 0\(\frac{1}{2}\)0, \(\frac{1}{2}\)0, \(\frac{1}{2}\)0, 0\(\frac{1}{2}\)0, \(\frac{1}{2}\)0\}\}. The phonon densities of states for the M1 and R phases are shown projected by atomic species in Fig. [4]. The eigenvectors of the imaginary transition modes are shown to project primarily onto the motion of vanadium atoms.

III. THERMODYNAMICS

The phonon entropy difference between the M1 and the R phases is estimated from the harmonic free energy

\[ S_{\text{ph}} = -\partial_T F_{\text{ph}}, \]

where \(F_{\text{ph}}\) is

\[ F_{\text{ph}} = -T \ln Z, \]

and partition function is computed using the harmonic geometric series expression

\[ Z = \prod_{n=1}^{\beta} \frac{e^{-\beta \omega_n/2}}{1 - e^{-\beta \omega_n}}, \]

with \(\beta = \frac{1}{T}\).

For the M1 phase, entropy is calculated from the standard DFT harmonic frequencies, \(\omega_n\). For the R phase the same expression is applied to the \(3n-2\) real harmonic DFT frequencies that don’t soften at the transition, and the two shifted frequencies \(\tilde{\omega}_n\), for the two imaginary harmonic modes subject to the experimental renormalization to real effective frequencies.

The R phase is metallic. As we are only interested in thermal electron excitations at moderate temperatures we assume \(\partial_T g(E) = 0\), and that electronic entropy of the R phase can be given in terms of partial one-electron occupancies as

\[ S_{\text{el}} = \int dE g(E) \{ f \ln f + (1 - f) \ln (1 - f) \}. \]

The total entropy of M1-VO2 is \(S_{\text{M1}} = S_{\text{M1}}^{\text{ph}}\), and the total entropy for R-VO2 is \(S_R = S_{R}^{\text{el}} + S_{R}^{\text{ph}} + S_{R}^{\text{el}}\). \(S_{\text{R}}^{\text{ph}}\) is the vibration contribution from the \(3n-2\) phonon modes that are harmonic at low temperature. \(S_{R}^{\text{el}}\) is from the dispersion bands that soften at the transition and is based on the frequencies transformed to \(T_C\).

IV. GAUSSIAN PROCESS REGRESSION

Supervised learning has been used to interpolate phonon frequencies using the non-parametric multivariate Bayesian method Gaussian Process Regression (GPR) [51]. GPR models can provide an appropriate alternative to Fourier interpolation, which is otherwise the method of choice when the full dynamical matrix is known. Without knowledge of the dynamical at the transition, GPR models can be used to directly interpolate frequencies in \(q\) space from limited \(\omega(q)\) experimental data points.

In this work we have used GPR for the \(q\)-space interpolation of the two renormalized soft modes in R-VO2.
The mode frequencies at $T_C$ are determined from experiment at limited high-symmetry wavevectors. GPR can be used to predict how $\tilde{\omega}(\mathbf{q})$ varies across the full Brillouin zone, making possible thermodynamic calculations for the high-temperature phase from limited high-temperature data points. To show that the GPR approach is appropriate to predict the full $\tilde{\omega}(\mathbf{q})$ surface from limited data points, we benchmark the accuracy of GPR interpolation on an analytic model.

Consider the vanadium-oxygen analytic model with the following dispersion relation

$$\tilde{\omega}(q_x, q_y) = \sqrt{\left(\frac{1}{m_O} + \frac{1}{m_V}\right) \pm \left(\left(\frac{1}{m_O} + \frac{1}{m_V}\right)^2 - \frac{4}{m_O m_V} \sin^2 q\right)},$$

which is shown in Fig. [5]. The test system includes features such as optic and acoustic-type dispersion, with frequencies that are non-linear in wavevector in more than one dimension and that have stationary points of inflection. The system is therefore expected to provide meaningful accuracy benchmarks, while also being simple enough to clearly illustrate the method.

In the test system $\tilde{\omega}(q_x, q_y)$ is sampled by a $100 \times 100$ mesh over $[0, \frac{\pi}{2}]$. GPR training data is a 1D scan of the mesh of $\tilde{\omega}(q_x, q_y)$ at the line-paths at $q_x = 0$ and at $q_x = \frac{\pi}{2}$. Root mean square (RMS) residual errors of the interpolated system compared to the true system are 5% for the acoustic band and 8% for the optic, with percentages calculated with respect to the maximum frequency value of $\tilde{\omega} = 0.54$ at $q = 0$. Typically we also know frequency gradients at zone boundaries. For a more realistic test model, derivatives at boundaries are included in the training set. This lowers RMS residual errors across $q$ to 2% and 3% for the acoustic and optic bands respectively.

In the GPR applied in this work, for the soft modes in R-VO$_2$, an analogous interpolation is made for the two transition bands in $\{q_x, q_y, q_z\}$. Errors of 2% for the interpolated R-VO$_2$ soft modes correspond to errors of approximately 1% or 0.01 $k_B$/VO$_2$ in the transition entropy difference, which is satisfactory within the scope of this work and in context of other sources of error.

To interpolate the R-VO$_2$ soft modes we have used a GPR with a non-deterministic radial basis function kernel of the form

$$k(q, q') = \sigma_f^2 \exp \frac{-(q - q')^2}{2l^2} + \sigma_n^2 \delta(q, q'),$$

with Bayesian maximum posterior $\theta = \{\sigma_f, \sigma_n, l\}$ hyperparameters. Training data includes line-paths between high-symmetry points in the $q_z = \frac{1}{2}$ and $q_z = 0$ planes, as well as zone boundary band velocities. GPR training data for soft modes in the $q_z = \frac{1}{2}$ plane consists of renormalized harmonic frequencies. These are sampled at 100-points/line for each edge in the cycle $\{R, Z, A, R\}$. For the $q_z = 0$ plane, in which the transition-mode bands do not soften at the transition, training data consists of 100-points/line samples of the edges in the $\{\Gamma, X, M, \Gamma\}$ graph for harmonic frequencies.
