In response to LIGO’s observation of GW170104, we performed a series of full numerical simulations of binary black holes, each designed to replicate likely realizations of its dynamics and radiation. These simulations have been performed at multiple resolutions and with two independent techniques to solve Einstein’s equations. For the nonprecessing and precessing simulations, we demonstrate that the two techniques agree mode by mode, at a precision substantially in excess of statistical uncertainties in current LIGO’s observations. Conversely, we demonstrate that our full numerical solutions contain information which is not accurately captured with the approximate phenomenological models commonly used to infer compact binary parameters. To quantify the impact of these differences on parameter inference for GW170104, we compare the predictions of our simulations and these approximate models to LIGO’s observations of GW170104.

I. INTRODUCTION

The LIGO-Virgo Collaboration (LVC) has reported the confident discovery of three binary black hole (BBH) mergers via gravitational wave (GW) radiation: GW150914\[^{[1]}\] and GW151226\[^{[2]}\] from the first observing run O1\[^{[3]}\], and GW170104\[^{[4]}\], GW170608\[^{[5]}\], and GW170814\[^{[6]}\] from the second observing run. The parameters of these detections were inferred by comparing the data to state-of-the-art approximate models\[^{[7–9]}\]. A reanalysis of GW150914 implementing full numerical relativity (NR)\[^{[10]}\] simulations helped to better constrain the mass ratio of the system. This is due to the fact that NR waveforms include physics omitted by current approximate models, notably higher order modes and accurate precession effects. A full description of this methodology, including detailed tests of systematic errors and parameter estimation improvements, can be found in Lange et al.\[^{[11]}\].

This paper is organized as follows. In Section II we describe the two independent techniques we use to solve Einstein’s equations numerically for the evolution of binary black hole spacetimes. In Section III we describe the binary’s parameters selected for detailed followup, our simulations of these proposed initial conditions, and detailed comparisons between our paired results, for both nonprecessing and precessing simulations. We also contrast our simulations’ radiation with the corresponding results derived from the approximate phenomenological models used by LIGO for parameter inference. In Section IV we directly compare our simulations to GW170104. These comparisons provide both a scalar measure of how well each simulation agrees with the data (a marginalized likelihood), as well as the best-fitting reconstructed waveform in each instrument\[^{[10,11]}\]. Using our reconstructed waveforms, we graphically demonstrate that our simulations agree with each other and the data, with simulation differences far smaller than the residual noise in each instrument. Using these real observations as a benchmark for model quality, we then quantify how effectively our simulations reproduce the data, compared to the results of approximate and phenomenological models at the same parameters. Since our simulations parameters were selected using these approximate and phenomenological models, we also have the opportunity to assess how effectively they identified the optimal binary parameters. In Section V we discuss the prospects for future targeted simulations in followup of LIGO observations.

II. FULL NUMERICAL EVOLUTIONS

The breakthroughs\[^{[12–14]}\] in numerical relativity allowed for detailed predictions for the gravitational waves from the late inspiral, plunge, merger and ringdown of black hole binary systems. Catalogs of the simulated waveforms are publicly available\[^{[15–17]}\] for its use for BBH parameter estimation\[^{[18]}\], as well as for determin-
ing how the individual masses and spins of the orbiting binary relate to the properties of the final remnant black hole produced after merger. This relationship can be used as a consistency check for the observations of the inspiral and, independently, the merger-ringdown signals as tests of general relativity [3, 20, 21].

### A. Simulations using finite-difference, moving-puncture methods

In order to make systematic studies and build a data bank of full numerical simulations, e.g., [17], it is crucial to develop efficient numerical algorithms, since large computational resources are required. The Rochester Institute of Technology (RIT) group evolved the BBH data sets described below using the LazEv [22] implementation of the moving puncture approach [13, 14] with the conformal function $W = \sqrt{\lambda} = \exp(-2\rho)$ suggested by Ref. [23]. For those runs, they used centered, sixth-order finite differencing in space [24] and a fourth-order Runge Kutta time integrator (the code does not upwind the advection terms) and a 5th-order Kreiss-Oliger dissipation operator.

The LazEv code uses the Einstein Toolkit [24-27] / Cactus [27] / Carpet [28] infrastructure. The Carpet mesh refinement driver provides a “moving boxes” style of mesh refinement. In this approach, refined grids of fixed size are arranged about the coordinate centers of both holes. The Carpet code then moves these fine grids about the computational domain by following the trajectories of the two BHs.

To compute the initial low eccentricity orbital parameters RIT used the post-Newtonian techniques described in [29] and then generated the initial data based on these parameters using approach [30] along with the TwoPunctures [31] code implementation.

The LazEv code uses AHFinderDirect [32] to locate apparent horizons, and measures the magnitude of the horizon spin using the isolated horizon (IH) algorithm detailed in Ref. [33] and as implemented in Ref. [34]. The horizon mass is calculated via the Christodoulou formula $m_H = \sqrt{m_{\text{intr}}^2 + S_H^2/\langle 4m_{\text{intr}}^2 \rangle}$, where $m_{\text{intr}} = \sqrt{A/(16\pi)}$, $A$ is the surface area of the horizon, and $S_H$ is the spin angular momentum of the BH (in units of $M^2$).

The radiated energy, linear momentum, and angular momentum were measured in terms of the radiative Weyl Scalar $\psi_4$, using the formulas provided in Refs. [35-36], Eqs. (22)-(24) and (27) respectively. However, rather than using the full $\psi_4$, it was decomposed into $\ell$ and $m$ modes and dropping terms with $\ell > 6$. The formulas in Refs. [35-36] are valid at $r = \infty$. To obtain the waveform and radiation quantities at infinity, the perturbative extrapolation described in Ref. [37] was used.

For the RIT simulations, different resolutions are denoted by NXXX where XXX is either 100, 118, or 140 for low, medium, and high resolutions, respectively. This number is directly related to the wavezone resolution in the simulation. For instance, N100 has a resolution of $M/1.0$ in the wavezone (where observer extraction takes place, preliminary to perturbative extrapolation to infinity via [37]), and N140 has $M/1.4$. In each case UID#1-5, there are 10 levels of refinement in all and the grids followed a pattern close to those described in [38].

Other groups using the moving punctures [13, 14] formalism with finite difference methods are Georgia Institute of Technology (GT) [16] and those based on BAM [39]. The GT [16] simulations were obtained with the Maya code [40-47], which is also based on the BSSN formulation with moving punctures. The grid structure for each run consisted of 10 levels of refinement provided by Carpet [28], a mesh refinement package for Cactus [27]. Each successive level’s resolution decreased by a factor of 2. Sixth-order spatial finite differencing was used with the BSSN equations implemented with Kranc [45].

### B. Simulations using pseudospectral, excision methods

Simulations labeled SXS are carried out using the Spectral Einstein Code (SpEC) [49] used by the Simulating eXtreme Spacetimes Collaboration (SXS). Given initial BBH parameters, a corresponding weighted superposition of two boosted, spinning Kerr-Schild black holes [50] is constructed, and then the constraints are solved [51-54] by a pseudospectral method to yield quasi-equilibrium [50-54] initial data. Small adjustments in the initial orbital trajectory are made iteratively to produce initial data with low eccentricity [55-57].

The initial data are evolved using a first-order representation [58] of a generalized harmonic formulation [59-61] of Einstein’s equations, and using damped harmonic gauge [62-64]. The equations are solved pseudospectrally on an adaptively-refined [65-66] spatial grid that extends from pure-outflow excision boundaries just inside apparent horizons [63, 67-70] to an artificial outer boundary. Adaptive time-stepping automatically achieves time steps of approximately the Courant limit.

On the Cal State Fullerton cluster, ORCA, the simulation achieved a typical evolution speed of $O(100M)/$day for the highest resolution (here we measure simulation time in units of $M$, the total mass of the binary). After the holes merge, all variables are automatically interpolated onto a new grid with a single excision boundary inside the common apparent horizon [67-68], and the evolution is continued. Constraint-preserving boundary conditions [58, 71-72] are imposed on the outer boundary, and no boundary conditions are required or imposed on the excision boundaries.

We use a pseudospectral fast-flow algorithm [73] to find apparent horizons, and we compute spins on these apparent horizons using the approximate Killing vector formalism of Cook, Whiting, and Owen [74, 75].
Gravitational wave extraction is done by three independent methods: direct extraction of the Newman-Penrose quantity $\Psi_4$ at finite radius \cite{55, 07, 76}, extraction of the strain $h$ by matching to solutions of the Regge-Wheeler-Zerilli-Moncrief equations at finite radius \cite{77, 78}, and Cauchy-Characteristic Extraction \cite{79-83}. The latter method directly provides gravitational waveforms at future null infinity, while for the former two methods the waveforms are computed at a series of finite radii and then extrapolated to infinity \cite{84}. Differences between the different methods, and differences in extrapolation algorithms, can be used to as error estimates on waveform extraction. These waveform extraction errors are important for the overall error budget of the simulations, and are typically on the order of, or slightly larger than, the numerical truncation error \cite{85, 86}. In this paper, the waveforms we compare use Regge-Wheeler-Zerilli-Moncrief extraction and extrapolation to infinity. We have verified that our choice of extrapolation order does not significantly affect our results. We have also checked that corrections to the wave modes \cite{87} to account for a small drift in the coordinates of the center of mass have a negligible effect on our results.

### III. SIMULATIONS OF GW170104

We extracted the maximum a posteriori (MaP) parameters from (preliminary) Bayesian posterior inferences performed by the LIGO Scientific Collaboration and the Virgo Collaboration, using different waveform models \cite{88, 89}. As described in Appendix B, this point parameter estimate is one of a few well-motivated and somewhat different choices for followup parameters; however, as described in that appendix, we estimate that the specific choice we adopt will not significantly change our principal results. Table I shows parameters simulated with numerical relativity.

Spin Conventions: ($\chi^x_i$, $\chi^y_i$, $\chi^z_i$) are specified in a frame where (i) $L = (0,0,1)$, i.e. the Newtonian orbital angular momentum is along the z-axis. (ii) the vector $\hat{n}$ pointing from $m_2$ to $m_1$ is the x-axis, (1,0,0). Note that the orientation of $\hat{n}$ is essentially undetermined by parameter estimation (PE) methods, so the choice (ii) is meant to break this degeneracy to arrive at concrete parameters. In other words, the spin-components given below are those consistent with Eqs. (9)-(11) of \cite{90}

The label, UID#1-5, of the simulation identifies which parameters we are using in following up as given by the initial data from Table I. For aligned spin runs, where spin-vectors are preserved, the initial orbital frequency may be smaller than $f_{ref}/2$. For precessing runs, because we target a certain spin configuration at $f_{ref}$, this forces the initial NR-frequency to be identical (or only somewhat smaller than) the reference frequency. $D/M$ is the initial orbital separation of the NR run in geometric units and the mass ratio and intrinsic spins ($\chi_i = S_i^2/m_i^2$) are denoted by ($q, \chi^x_1, \chi^y_1, ..., $). Due to the way NR simulations are set-up the initial parameters can change due to the presence of junk radiation and/or imperfections in setting up initial data, therefore these quantities should be reported as after-junk masses/spins, ideally extracted at the reference frequency. For precessing runs, in particular, the spin-components should be specified at the reference frequency, following the convention $\chi^i = \chi_i \cdot \hat{n}, \chi^j = \chi_i \cdot \hat{L}$, with $\hat{n}$ and $\hat{L}$ computed at the reference frequency, too. We also provide $e$, the orbital eccentricity. For instance, the actual initial data as measured for the RIT’s followup simulations are described in Table III.

For followup #1, the initial spurious burst contains a non-negligible kick which causes a center of mass drift of approximately 0.65M over the 4000M of evolution. Because of this, information from the dominant $\ell = 2, m = \pm 2$ modes leak into the other modes, particularly the $m = \text{odd}$ modes. To reduce this effect, we can recalculate the modes by finding the average rest frame of the binary. We calculate the average velocity of the center of mass of the binary (from $\psi_4$) over the inspiral and then boost the waveform in the opposite direction. This is done using Eqs. (4-5) in \cite{91} and Eqs. (7-8) in \cite{92}. Note that this does not change the physical waveforms, only how they are spread over modes.

For the RIT simulations, the initial data parameters in Table I for the nonprecessing systems 1, 4, and 5 were determined by choosing the starting frequency just below the reference frequency. This gives the gauge time to settle, and since the spins do not change, this gives us a cleaner waveform once we hit the reference frequency. For the precessing simulations 2 and 3, since the spins will now evolve, we determine the initial data parameters by choosing the initial spins at the specified reference frequency. The initial data used by SXS, being not conformally flat have less spurious radiation content than the Bowen-York data and hence produce a different set of masses and spins after settling down. See Table III for the specific values of each simulation by the two kind of initial data families. This process can be iterated to get closer initial parameters for each approach, although it requires some extra evolution time and coordination to reach a fractional agreement below $10^{-3}$. This process has been followed for UID#1, but not for the other cases, in particular the two precessing ones #2 and #3, and hence the differences, for instance, displayed in Fig. I for the precessing case #3.

The SXS simulations used in this work have been assigned SXS catalog numbers BBH:0626 (UID1), BBH:0627 (UID2), BBH:0628 (UID3), BBH:0625 (UID4), and BBH:0631 (UID5).

Each simulation has an asymptotic frame relative to which we extract $r h_{m}(t)$. In all cases used here, this axis corresponds to the $\hat{z}$ ($= \hat{L}$) axis of the simulation frame. For all simulations, this axis also agrees with the orbital angular momentum axis $\hat{L}$ at the start of the evolution.

A. Outgoing radiation very similar for different NR methods

Following previous studies [93], we compare the outgoing radiation mode by mode, using an observationally-driven measure: the overlap or match. The black and grey lines in Figures 2 and 3 show the match between the two simulations’ (RIT-SXS and RIT-GT respectively) (2,2) modes, as a function of the minimum frequency used in the match. In this calculation, we use a detector noise power spectrum appropriate to GW170104, and a total mass $M_{\odot}$ as given in Table I. By increasing the minimum frequency, we increasingly omit the earliest times in the signal, first eliminating transient startup effects associated due to finite duration and eventually comparing principally the merger signals from the two black holes. For comparison, the red, blue, and yellow lines show the corresponding matches between RIT, SXS, and GT simulations respectively and effective one body models with identical parameters (faithfulness study). In Figure 2, which illustrates only nonprecessing simulations, these comparisons are made to the nonprecessing model SEOBNRv4 [94]. In Figure 3, which targets the two precessing UIDs, we instead compare to SEOBNRv3, which approximates some precession effects. For both nonprecessing and precessing simulations, these figures show that the different NR groups’ simulations produce similar radiation, with mismatches $\lesssim 10^{-3}$ even at the longest durations considered. By contrast, comparisons with SEOBNRv4 and SEOBNRv3 show that these models do not replicate our simulations’ results, particularly for precessing binaries.

To demonstrate good agreement beyond the (2,2) mode for precessing simulations, for multiple resolutions, Tables IV and V systematically compare all modes between RIT and SXS. The match calculations in this Table are performed using a strain noise power spectral densities (PSD) characterizing data near GW170104. Following [93], one phase- and time-shift is computed by maximizing the overlap of the (2,2) mode; this phase- and time-shift is then applied to all other modes without any further maximization. Table IV shows a resolution test: the match between RIT and SXS simulations, as a function of RIT simulation resolution. As the most challenging precessing case, UID3 is shown by default. For the $m = 0$ modes, all the simulations show good agreement mode-by-mode, for all resolutions.

Based on Figures 2, 3 and Table IV we anticipate the lowest production-quality NR resolution (N100 for RIT; L3 for SXS) will usually be sufficient to go well beyond the accuracy of approximate and phenomenological models. To elaborate on this hypothesis, Table V shows the mode-by-mode overlaps between these two lowest NR resolutions. The $\ell = 2$ modes agree without exception. Good agreement also exists for the most significant modes up to $\ell \leq 4$. On the other hand, the last columns of Table IV shows that the rough agreement between NR and models for the modes (2,2) displayed in Fig. 3 notably worsens when looking at other than the leading modes.

In Table VI, we also provide a comparison of the remnant properties, i.e. final mass, spin and recoil velocity of the final, merged, black hole, as computed by the two NR methods and for a set of three increasing resolutions. We observe good agreement and convergence of their values. In the case of the RIT runs, a nearly 4th order convergence with resolution for the recoil velocity of the rem-
null
TABLE IV. Match between individual spherical harmonic modes \((\ell, m)\) of the SXS and RIT UID3 waveforms, using the H1 PSD characterizing data near GW170104. Following [93], rather than maximize over time and phase for each independently, our mode-by-mode comparisons fix the event time and overall phase using one mode (here, the (2,2) mode). The successively higher resolution simulations from RIT, labeled as \(N_{100}, N_{118}, N_{140}\) are compared to the L3 (highest) resolution run from SXS. The minimal frequency is taken as \(f_{\text{min}} = 30\) mHz for \(m > 1\) and \(f_{\text{min}} = 30\) Hz for \(m = 0, 1\) for a fiducial total mass of \(M = 58.73 M_\odot\). The column labeled \(M_3\) shows the match between RIT N140 and the corresponding SEOBNRv3 mode. Rows with a “-” are not modeled by SEOBNRv3. The column labeled \(O_{N140}\) shows the overlap of N140 with itself, with a minimum frequency of 30 Hz in all cases, to indicate the significance of the mode.

| \(\ell\) | \(m\) | \(N_{100}\) | \(N_{118}\) | \(N_{140}\) | \(M_3\) | \(O_{N140}\) |

FIG. 1. The small BH (top) and large BH (bottom) spins for followup #3. RIT’s simulation has solid lines; SXS’s has dashed lines; and spin evolution as predicted by SEOBNRv3 is shown with a wide-dashed line. The spin components, \(x\), \(y\), and \(z\), are red, blue, and green respectively.

pare these observations to the corresponding predictions of approximate and phenomenological models that purport to describe the same event.

Figure 4 displays the direct comparison of the non-precessing simulations by RIT and SXS complementary approaches for the configurations UID#1, UID#4, and UID#5, as given in Table II. They directly compare to the signals as observed by LIGO H1 and L1 and with each other. The lower panel shows the residuals of the signals with respect to the RIT N118 simulation and compares it with the direct difference of the two approaches and also with the difference of the N118 and N100 resolutions, that measure the finite difference error of the N118, given the observed near 4th order convergence seen when included the N140 run into the analysis. For all three cases we note that the differences in any of the simulations is much smaller than the residuals and hence typical noise of the observations. This shows that the fast response runs performed to simulate BBH (low-medium resolution) are in an acceptable good agreement with the expected higher resolution ones at the required level of errors.
Figure 5 displays the two precessing targeted simulations for GW170104 studied in this paper. We compare them with the L1 and H1 signals in grey and light grey in the plots. Here we also perform a double test of the accuracy of the simulations by considering the two main approaches to solve BBHs by the RIT and SXS groups and by considering the internal consistency of convergence of the waveforms with increasing resolutions. The waveforms again show a good agreement among themselves and their differences, shown in the lower panels are smaller than the residuals of the signals with respect to the N118 simulations. They are larger than in the aligned cases due to the choice of the initial spin configurations at at slightly different reference orbital frequencies. Note also that this comparisons do not align the peak of the waveforms and hence if independently fit to data would show much smaller differential residuals.

### A. Residuals versus resolution

For each UID, direct comparison of our simulations to the data selects a fiducial total mass which best fits the observations, as measured by the marginalized likelihood of the data assuming our simulations. Using the same mass for all simulations performed for that UID (e.g., by all groups and for all resolutions), we can for each simula-
TABLE VI. Remnant results for spinning binaries. We show the remnant mass \(m_{\text{rem}}\) in units of the total initial mass \(M \equiv m_1 + m_2\), the remnant dimensionless spin \(\chi^z_{\text{rem}} \equiv J^z_{\text{rem}}/m^2_{\text{rem}}\), and the remnant velocity in the x-y plane \(V_{\text{rem}}^{xy}\). We show results for different LazEv resolutions (N100, N118, and N140) and different SpEC resolutions (L0, L2, L4, and L6).

| #     | \(m_{\text{rem}}/M\) | \(\chi^z_{\text{rem}}\) | \(V_{\text{rem}}^{xy}\) (km/s) |

FIG. 2. For the three nonprecessing UIDs # 1,4,5 in Table II matches between SXS, RIT, and SEOBNRv4 (2,2) modes as a function of \(f_{\text{min}}\), using the H1 PSD characterizing data near GW170104. We also compare with GT runs for UIDs # 4,5. Compare to also to similar plots for GW150914 [10]. The top panel shows the residuals, and the difference between the two simulations in green. Note that the difference between waveforms is small compared to the residuals, but enough to make the simulation in blue (top candidate in Table VIII) have a slightly higher Likelihood (63.0 vs. 62.5) over UID#1 in red, to match the signals over the
According to the variations in the Table VII that evaluated for the different resolutions we may derive as a rule of thumb that the N100 grid provides a good approximation for the nonprecessing binaries, while for the precessing ones, N118 is more appropriate. This leads to a reduction of the SUs needed for these 5 simulations, totaling nearly 1 million SUs, two thirds of which are due to the two precessing cases. The pseudospectral approach used by the SXS collaboration requires similar total wallclock times than the above finite differences approach, but spends an order of magnitude less resources. For instance, UID#1 (SXS:BBH:0626) required 11 kSUs, while UID#5 (SXS:BBH:1321) required 4.7 kSUs hours for Lev2.

### B. Likelihood of NR and models

For any proposed coalescing binary, characterized by its outgoing radiation as a function of all directions, we can compute a single quantity to assess its potential similarity to GW170104, accounting for all possible ways of orienting the source and placing it in the universe: the marginalized likelihood (\(\ln L_{\text{marg}}\)) \([18, 99, 100]\). To produce an alternative evaluation of the errors within a given NR method.

The studies carried out in this paper involving 3-resolutions for each set of parameters well in the convergence regime of the simulations can be very costly from the resources point of view, totaling over 4 million service units (SUs) in computer clusters, as detailed in Table IX.

According to the variations in the Table VII and evaluated \(\ln L\) for the different resolutions we may derive as a rule of thumb that the N100 grid provides a good approximation for the nonprecessing binaries, while for the precessing ones, N118 is more appropriate. This leads to a reduction of the SUs needed for these 5 simulations, totaling nearly 1 million SUs, two thirds of which are due to the two precessing cases. The pseudospectral approach used by the SXS collaboration requires similar total wallclock times than the above finite differences approach, but spends an order of magnitude less resources. For instance, UID#1 (SXS:BBH:0626) required 11 kSUs for Lev4, 7.4 kSUs for Lev3, and 4.7 kSUs hours for Lev2.

**TABLE VII. Marginalized likelihood of the data:** This table shows the results for the 5 simulations when directly compared to the data. For these results, we use the same PSD adopted in all other calculations, with \(f_{\text{min}} = 30\text{Hz}\) (i.e. low-frequency cutoff). The first column is the UID. The second column is the estimated peak log marginalized likelihood \(\ln L\), maximized over binary total mass, for the NR followup simulation. The third column is the corresponding log marginalized likelihood, using exactly the same intrinsic parameters (e.g., masses and spins) as maximize the likelihood in the second column, evaluated using a phenomenological approximate model instead of numerical relativity. The fourth column is the specific model used: either SEOBNRv3 (for precessing simulations) or SEOBNRv4 (for nonprecessing simulations). To see more on this parameter estimation method, see [10,11].

| UID  | \(\ln L\) (RIT) | \(\ln L\) (SXS) | \(\ln L\) (GT) | \(\ln L\) (SEO) | Model |
|------|-----------------|-----------------|---------------|----------------|-------|
| #1   | 60.4 61.0 61.0  | 60.9            | -             | 62.7           | v4    |
| #2   | 61.0 60.9 60.6  | 60.9            | -             | 61.4           | v3    |
| #3   | 60.4 60.5 60.7  | 60.7            | -             | 60.4           | v3    |
| #4   | 60.6 60.7 60.8  | 60.3            | 60.4          | 62.2           | v4    |
| #5   | 60.0 60.0 60.1  | 60.0            | 59.8          | 61.2           | v4    |

The whole range of frequencies considered. The same simulation resolution have been considered in both cases.

We have also analyzed the finite differences errors produced by fast-response, low resolution (yet in the convergence regime) simulations of BBH mergers. The low, medium and high resolutions runs, N100, N118, and N140 respectively, by the RIT group show a nearly 4th order convergence (There are detailed studies of convergence for similar simulations in Refs. [19, 38, 95] that allow to extrapolate to infinite resolution and evaluate the magnitude of the errors in the waveforms as compared to the residuals for this GW170104 event. We thus can evaluate the error of the N118 simulation is given by the (N100-N118) difference, while the error of the N100 waveform is twice this difference and that of the N140 waveform is half that difference. This is displayed in the lower half of each panel in Figs. 4 and 5 and provide an alternative evaluation of the errors within a given NR method.

FIG. 3. For the two precessingUIDs#2,3 in Table IV matches between SXS, RIT, and SEOBNRv3 (2,2) modes as a function of \(f_{\text{min}}\) as a function of \(f_{\text{min}}\) using the H1 PSD characterizing data near GW170104. In this comparison, the (2,2) mode of all three simulations and SEOBNRv3 are extracted relative to the \(L\) axis, identified from their common initial orbital parameters. While these frame identifications are coordinate-dependent for precessing binaries – implying our comparisons could include both intrinsic disagreement and systematic error due to (say) overall misalignment – the good agreement shown in Figure 1 for the equally coordinate-dependent spins suggests that convention-dependent sources contribute little to the mismatches illustrated here.
FIG. 4. Comparison of the GW170104 signal seen by LIGO detectors H1 and L1 (in grey and dark grey) with the computer simulations of black hole mergers from SXS, RIT, and GT approaches for the nonprecessing cases labeled as #1, #4, and #5 in Table II.
TABLE VIII. Marginalized likelihood of the data: Selected other simulations: This table shows the results for several other simulations that particularly match the data well and the SEOB model results at those parameter points. These simulations are part of the top 15 simulations in $\ln L$. When comparing the NR $\ln L$ values here to the ones in Table VII, one can see these to be generally higher i.e. better match the data. When comparing the NR $\ln L$ values to the SEOB at the same points, one sees a consistent lower SEOB $\ln L$ value. This implies that these points were not picked for NR Followup due to the lower SEOB $\ln L$ value.

![Comparison of the GW170104 signal seen by LIGO detectors H1 and L1 (in grey and dark grey) with the computer simulations of black hole mergers from SXS and RIT approaches for the nonprecessing cases labeled as #2 and #3 in Table II.](image)

**FIG. 5.** Comparison of the GW170104 signal seen by LIGO detectors H1 and L1 (in grey and dark grey) with the computer simulations of black hole mergers from SXS and RIT approaches for the nonprecessing cases labeled as #2 and #3 in Table II.
To provide a sense of scale, the distribution of ln $L_{\text{marg}}$ over the posterior distribution including all intrinsic parameters is roughly universal \[100\], approximately distributed as \(\ln L_{\text{marg}, \max} - \chi^2/2\) where \(\chi^2\) has \(d\) degrees of freedom (i.e., a mean value of \(\ln L_{\text{marg}, \max} - d/2\), and its 90\% credible interval is \(\ln L_{\text{marg}} \geq \ln L - x\), where \(x = 3.89\) and \(x = 6.68\) for \(d = 4\) and \(d = 8\), respectively). For each UID and for each proposed total mass \(M\), direct comparison of our simulations to the data allows us to compute a single number measuring the quality of fit: the marginalized likelihood \(L_{\text{marg}}\). The maximum value of this function (here denoted by \(L\)) therefore measures the overall quality of fit. Table \(\text{VII}\) shows \(L\) for the five UIDs simulated here. For comparison, the last column shows \(L\) calculated using an approximate model for the radiation from a coalescing binary. Obviously, if these approximate models and our simulations agree, then we should find the same result for \(L\) at the same parameters. Finally, for context, the peak value of \(\ln L\) computed using SEOBNRv3 with generic parameters is 63.3. If our simulation parameters are well-chosen (and if both our simulations and these models are close to true solutions of Einstein’s equations), then this peak value should be in good agreement with the \(\ln L\) evaluated using our simulations.

First and foremost, up to Monte Carlo and fitting error, the marginalized likelihoods calculated with NR agree with each other comparing different resolutions and different approaches to solve the BBH problem, as required given the high degree of similarity between the underlying simulations. Second, the marginalized likelihoods computed at these proposed points are substantially below the largest \(L\) found with approximate models like SEOBNRv3, except for UID3. Similar to the explanation described in Appendix \(\text{B}\), the exception here is due to the differences between the precessing models (in \(\ln L\) was calculated with SEOB, but the parameters were suggested with IMRP). Likewise, the binary parameters at which the peak value of \(L\) occurs for SEOBNRv3 are substantially different from any of the proposed parameters explored here. This discrepancy suggests that the model-based procedure that we adopted to target our followup simulations was not effective at finding the most likely parameters, as measured with \(\ln L\). The poor performance of our targeted followup cannot simply reflect sampling error; even though the likelihood surface is nearly flat near the peak, so small errors are amplified in parameter space, this near-flatness also insures that systematic offsets \textit{should} produce a small change in \(L\), if the underlying waveform calculations agree; see Appendix \(\text{B}\) for further discussion. Instead, we suspect the biases in \(L\) arise because the models only approximate the correct solution of Einstein’s equations. Third, we confirm our hypothesis in Table \(\text{VII}\) simply by demonstrating that other simulations (not performed in followup) fit the data substantially better than our targeted parameters.

On the one hand, NR followup simulations guided by the models (as displayed in Table \(\text{VII}\)) leads to lower marginalized likelihoods (\(\ln L\)). Conversely, other simulations shown in Table \(\text{VII}\) produce higher \(\ln L\), at points in parameter space where the models predict lower \(\ln L\). This discrepancy suggest the two processes (\(\ln L\) evaluated with NR and with the models) favor different regions of parameter space. In particular, table \(\text{VII}\) which has one of the largest values of \(\ln L\) among all of the (roughly two thousand) simulations available to us, shows that the top precessing simulation is \(q50_a0_a8_th_135_ph_30\). This simulation has a mass ratio of 1:2, i.e. \(q=1/2\), where the smaller hole is nonspinning and the larger hole is spinning with an intrinsic spin magnitude of 0.8 and pointing initially in a direction downwards with respect to the orbital angular momentum (\(\theta=135\) degrees) and an angle of 30 degrees from the line joining the two black holes (\(\phi=30\) degrees). This simulation belongs to a family of 6 simulations performed in Ref. \(\text{101}\) labeled as NQ50TH135PH[0,30,60,90,120,150]. Those runs, supplemented by two control runs with angles \(\phi = 200, 310\) we performed for this paper, are displayed in Fig. \(\text{7}\) versus the \(\ln L\) for this GW170104 event. The lower panels plots all those simulation with respect to their \(\phi\)-angle at merger as defined in Ref. \(\text{101}\) and given in table XXI in that paper. The continuous curve provide a fit (detailed in table \(\text{X}\)) for such values as reference and an estimate of the maximum value located near the \(\phi=30\) simulation.

The notable results displayed in Fig. \(\text{7}\), where \(\ln L\) seems to be sensitive to the orientation of the spin of the larger hole on the orbital plane, are consistent with broader trends that can be extracted using similar simulations: here, the set of 24 simulations of the family NQ50TH[30,60,90,135]PH[0,30,60,90,120,150] given in Ref. \(\text{101}\) supplemented by the two aligned runs NQ50TH[0,180]PH0 given in Ref. \(\text{105}\) and two runs specifically performed for this paper, NQ50TH135PH[200,310]. These simulations all have \(q = 1/2\), a nonspinning smaller BH, and a spinning BH with fixed spin magnitude but changing orientation. Figure \(\text{8}\) shows a color-map derived from the maximum \(\ln L\) obtained for each of these simulations, using standard (MatLab) plotting tools. The last surface levels indicates the regions of largest likelihood (60,61,62) and a maximum, marked with an X, is located at TH=137, PH=87 with \(\ln L\) of 62.6. This results allow us to perform followup simulations seeking for this maximum.

TABLE IX. kSUs (1000 core-hours) for each RIT run and resolution.
FIG. 6. Comparison of the GW170104 signal seen by LIGO detectors H1 and L1 (in grey and dark grey) with the computer simulations of black hole mergers from RIT at low resolution for the nonprecessing case labeled as #1 in Table II and the highest ln \( L \) value for an NR simulation given in Table VIII (d0_D1052_q1.3333_a-0.25_n100).

| \( \phi \) | \( \phi_{\text{merger}} \) | ln \( L \) | \( M_2/M_\odot \) |
|---|---|---|---|
| 0 | 0 | 62.3 | 54.9 |
| 30 | 19.5 | 62.5 | 55.2 |
| 60 | 34.8 | 62.2 | 54.1 |
| 90 | 56.5 | 62.5 | 54.4 |
| 120 | 98.5 | 61.6 | 54.1 |
| 150 | 146.5 | 60.6 | 54.5 |
| 210 | 194.7 | 59.3 | 55.1 |
| 310 | 294.0 | 60.4 | 54.6 |

\[ A \quad B \quad C \quad \text{RMS} \]

1.23 ± 0.21 | −0.75 ± 0.15 | 61.1 ± 0.15 | 0.38

\[ A_{\text{merger}} \quad B_{\text{merger}} \quad C_{\text{merger}} \quad \text{RMS}_{\text{merger}} \]

1.08 ± 0.18 | −0.47 ± 0.19 | 61.1 ± 0.15 | 0.37

TABLE X. The log-likelihood of the NQ50TH135 series [101]. Fittings of the form ln \( L \) = Asin(\( \pi \)/180\( \phi \)) + \( B \) + \( C \) is also given for both the initial \( \phi \) and \( \phi_{\text{merger}} \).

In the plot, the black points are the NR simulations and the black curves are level sets of the color-map. Instead of plotting in the angles theta and phi, we plot in the Hammer–Aitoff coordinates [102], which is a coordinate system where the whole angular space can be viewed as a 2d map. The points at the top left and bottom left are the poles, \( \theta = 0 \) at the top, and \( \theta = \pi \) at the bottom. The line connecting the two is the \( \phi = 0 \) line.

As you move from left to right, \( \phi \) increases from 0 to 150 degrees (the maximum value of \( \phi \) available in these simulations).

C. Reconstructed NR waveforms

The analysis above – a difference in ln \( L \) for models that should represent the same physical binary which is comparable to the expected range of ln \( L_{\text{marg}} \) over the posterior – suggests modest tension can exist between our NR simulations and the models used to draw inferences about GW170104. To illustrate this tension, in Fig. 9 we display the 90% confidence intervals of the precessing follow up cases (#2 and #3) computed by the two approximate/phenomenological models comparing them with the full numerical simulations (RIT’s with N100 resolutions, note that increasing the numerical resolutions to N118 and N140 reinforces this point). For each simulation, the waveform is generated by first fixing the total mass – selected by maximizing \( L \) – and then choosing extrinsic parameters which maximize the likelihood. At merger, these reconstructed waveforms appear to be in modest tension with the confidence interval reported for \( h(t) \); for example, the peaks and troughs of the yellow (NR) curves are consistently at the boundaries of what the 90% credible intervals derived from waveforms allow. This illustration, however, relies on a non representative metric to assess waveform similarity (i.e, differences in
FIG. 7. The log-likelihood of the NQ50TH135 series assuming a period of $2\pi$ versus initial angle (top panel) and merger angle (bottom panel.) Data (red) and fits (blue) are given in Table X.

FIG. 8. The log-likelihood of the NQ50THPHI series as a color map with red giving the highest $\ln \mathcal{L}$ and blue the lowest. The black dots (and grey diamonds, obtained by symmetry) represent the NR simulations and we have used Hammer-Aitoff coordinates $X_{HA}, Y_{HA}$ to represent the map and level curves with the top values of $\ln \mathcal{L} = 60, 61, 62$. The maximum, marked with an X, is located at TH=137, PH=87 reaching $\ln \mathcal{L} = 62.6$.

FIG. 9. Comparison of the 90% confidence intervals of GW170104 from the two precessing models with the computer simulations of black hole mergers (in orange) from the best-fitting NR simulations listed in Table VIII. The GW strain as a function of time, without reference to detector sensitivity, assessed by eye).

To remedy this deficiency, Figure 10 uses the match to compare our reconstructed NR waveforms with reconstructed waveforms drawn from the posterior parameter distribution of GW170104. The top panel uses a violin plot to illustrate the distribution of matches, with a solid bar showing the median value. The bottom panel shows a sample cumulative distribution. The median and maximum of this distribution provides a measure of how consistent the $h(t)$ estimate via NR is with the distribution provided by the model. Using the maximum likelihood waveform from the model and posterior, these distributions should be proportional to a (centrally) $\chi^2$ distributed quantity, with median mismatch $N/2\rho^2$ for $N$ the number of model degrees of freedom and $\rho$ the signal to noise ratio (SNR), where the specific choice for $\rho$ depends on the signal and detector/network being studied (e.g., for GW170104, the network SNR was $\simeq 13$). By contrast, in several of these overlap distributions, the peak and median values are manifestly offset downward, supporting a significant systematic difference between the radiation predicted from our approximate models and our NR waveforms, each generated from targeted NR followup simulations using parameters drawn from these selfsame model parameter distributions.

D. Discussion

Using comparisons to data via $\ln \mathcal{L}$ as our guide, we found in Section IV B that model-based and NR-based analyses seem to have maxima (in $\ln \mathcal{L}$) in different parts
of parameter space; see Appendix B for greater detail.
In the region identified as a good fit by model-based analysis, corresponding NR simulations have a low ln \( L \). If an NR signal is perfectly consistent with these models for some parameters, then the distribution of matches will be well-approximated by a \( \chi^2 \) distribution with \( d - 1 \) degrees of freedom. Many of the best-fitting NR simulations have a distribution of matches that is significantly offset relative to this expected distribution, reflecting the mild tension shown in Figure 9.

The NR followup simulations and Bayesian inferences used in this work were performed soon after the identification of GW170104, and as such did not benefit from recent improvements in waveform modeling. Notably, by calibrating to a large suite of numerical relativity simulations, surrogate waveform models have been generated that, in a suitable part of parameter space, are markedly superior to any of the waveform models used for parameter inference to date. Parameter inferences performed with these models should be more reliable and (by optimizing ln \( L \)) enable better targets for NR followup simulations.

For simplicity and brevity, we have directly compared our nonprecessing and precessing simulations to only one of the two extant families of phenomenological waveform models (SEOBBv3/v4). While the two models are in good agreement for nonprecessing binaries, the other model (IMRP) has technical complications that limit its utility for our study. On the one hand, we cannot generate a similar waveform with similar initial conditions, prevented from performing the straightforward comparisons shown in Figure 3. As a frequency domain model, it did not adopt the same time conventions as NR and time-domain models for the precession phase (see, e.g., Williamson et al 2017 [105].) On the other hand, the implementations available do not provide a spin-weighted spherical harmonic decomposition, preventing us from performing the mode-by-mode mismatch calculations in Table IV.

Previous investigations have demonstrated by example that posterior inferences with approximate waveform models can be biased, even for parameters consistent with observed binary black hole 105,106. For example, a previous large study using simulations consistent with GW150914 found that, despite the brevity and relative simplicity of its signal, the inferred parameters could be biased for certain binary configurations relative to the line of sight 106, and much less so for others (e.g., nonprecessing and comparable-mass binaries). The relevance and frequency of these configurations is not yet determined and depends on the binary black hole population which nature provides.

V. CONCLUSIONS

After the detection of GW170104 [88], we performed several simulations of binary black hole mergers, intending to reproduce LIGO’s observations using simulations with similar parameters. The parameters used were selected based on LIGO’s reported inferences about GW170104, generated by comparing two approximate models for binary black hole merger to the GW170104 data. Comparing these targeted simulations of binary black hole mergers, we find good agreement. We have shown that the differences among typical numerical simulations, used as a measure of their error, is much smaller (by over an order of magnitude) than the residuals of observation versus theory. On the other hand, we demonstrate (expected) differences between our numerical solutions to general relativity and the approximate models used to target our simulations. Because we used these models to identify candidate parameters for followup, our followup simulations were systematically biased away from the best-fitting parameters. These biases...
are not surprising, as the models used do not fully incorporate all the physics of binary merger, including higher modes and all features of precession, and are known to modestly disagree both with one another and with NR simulations. This does not mean that the models are not recovering the full signal: both models and NR could find similar likelihoods, but for different parameters. These bias can be particularly large for small mass ratios and highly spinning precessing binaries. We demonstrate that other, pre-existing simulations with different parameters fit the data substantially better than the configurations targeted by model-based techniques.

We have shown here (and in previous studies [18, 107]) that the standard low resolution, fast-response, simulations provide an accurate description of GW signals, and can improve over the parameters determined by the models (See Table VIII and Fig. 7) for precessing and non-precessing cases (note that while SEOBNrv4 improves on the inaccurate [93] SEOBNrv2 [118], it is still not at comparable accuracy to the NR simulations, See Figs. 2 for instance). The tension between the models and the full numerical simulations (notwithstanding [109]) may be crucial in determining parameters such as individual spin of the holes and tests of general relativity for the large SNR signals, where the limitations of the models is larger). Both this study, focused on GW170104, and the investigation by [105], carried out on GW151226, point to the limitations of existing models to accurately determine binary parameters in the case of precessing BBH.

Regarding prospects for future followups, Figure 11 shows the distributions of the minimal total mass of the BBH systems in the NR catalogs [15–17] given a starting gravitational wave frequency of 20 or 30 Hz in the source frame and its cumulative. This provides a coverage for the current events observed by LIGO (redshift effects improve this coverage by a factor of \((1 + z)\), where \(z\) is the redshift). Coverage of lower total masses would require longer simulations or hybridization of the current waveforms.

Finally, we demonstrated the power of using purely numerical waveforms to determine parameters of a binary black hole merger as the previous case of GW150914 [100] and similarly in the case of the source GW170104. More work is needed though to systematically and robustly include hybridization of waveforms and the case of generically precessing binaries [118].

Appendix A: Impact of discrete posterior sampling

In the text, we performed several calculations that depend on an inferred posterior distribution: identifying parameters for NR followup calculations; maximizing the marginalized likelihood \(\ln L\); and calculating mismatches. These calculations are performed using a finite-size collection of approximately independent, identically-distributed samples from a posterior distribution \([89]\).

In this appendix we briefly quantify the (small) effects our finite sample size has on our conclusions and comparisons. For simplicity, we will conservatively standardize our calculations to \(N = 3000\) posterior samples; in practice, usually many more were used.

The match and marginalized likelihood distributions are well-described by a \(\chi^2\) distribution with a suitable number of degrees of freedom, corresponding to the model dimension of the intrinsic parameter space (i.e., \(d = 4\) for calculations which omit precession, and \(d = 8\) for calculations which include it). For example if \(\ln L\) is the true maximum marginalized likelihood, then the marginalized likelihood distribution over the posterior is well-approximated by the distribution of \(\ln L = \ln L_{\text{max}} - x/2\) where \(x = \chi^2\) distributed with \(d\) degrees of freedom. If we have \(N\) independent draws from the \(\chi^2\) distribution, the smallest value of \(x\) will be distributed according to \(P(x > d|N) = (1 - P(x < d|N))^N\), where \(P(x < d|N)\) is the cumulative distribution for the \(\chi^2\) distribution. At 95% confidence, the maximum value of \(x\) over the \(N\) samples is therefore \(P^{-1}(0.05^{1/N})\). As a result, if we estimate the maximum value of \(\ln L\) with the maximum over our posterior samples, we find an estimate which is smaller than the true maximum value \(\ln L_{\text{max}}\) by \(0.5P^{-1}(0.05^{1/N})\).

Evaluating this expression for \(d = 4\) and \(d = 8\) in the conservative limit of only \(N = 3000\) samples, we find a systematic sampling error of 0.045 (0.31) in \(d = 4\) \((d = 8)\), respectively, in our estimate of the peak marginalized likelihood. This systematic sampling error in our estimate of the peak marginalized likelihood is smaller than the differences in marginalized likelihoods discussed in the text and figures.

Likewise, given the number of samples, the targeted parameters should be very close to the true maximum a posteriori values. Qualitatively speaking, due to finite sample size effects, our estimate of each parameter \(z\) has an uncertainty of roughly \(\sigma_z/\sqrt{N}\), or roughly 2% of the
width of the distribution using our fiducial sample size.

Appendix B: Mixed messages: Maximum likelihood, \( \ln \mathcal{L} \), and a posteriori

One goal of this work is to demonstrate, by a concrete counterexample, that NR followup must be targeted and assessed self-consistently.

One source of inconsistency in our original NR followup strategy was the algorithm by which NR simulations were selected from model-based inference. Our NR followup simulations were selected by (approximately) maximizing the a posteriori probability, proportional to the (15-dimensional) likelihood \( L \); the (7-dimensional) prior \( p(\theta) \) for extrinsic parameters \( \theta \); and the (8-dimensional) prior for intrinsic parameters \( p(\lambda) \). This maximum a posteriori (MaP) location does not generally correspond to the parameters which maximize the likelihood (maxL). The intrinsic parameters selected by both approaches also do not cause the marginalized likelihood \( \mathcal{L}_{\text{marg}}(\lambda) = \int d\theta p(\theta) L(\lambda, \theta) \) to take on its largest value. In principle, to avoid introducing artificial inconsistencies simply due to the choice of point estimate, we should have targeted followup simulations using \( \ln \mathcal{L} \). To assess how much our choice of targeting impacted our estimate of \( \ln \mathcal{L} \), we evaluated the marginalized likelihood at our estimates of all three locations. Each location was approximated by our (finite-size) set of posterior samples. For the posterior distribution adopted to generate UID4 – a nonprecessing production-quality analysis where SEOBNRv4 was both used to generate the reference posterior used to find the MaP and maxL parameters and to compute a model-based \( \ln \mathcal{L} \) – we find that the model-based \( \ln \mathcal{L} \) values at the MaP and maxL points to be effectively indistinguishable due to Monte Carlo error (61.4 and 61.2 respectively, with an estimated Monte Carlo error of 0.1). This similarity suggests that, when a fully self-consistent analysis is performed, then even if the MaP and maxL parameters differ slightly, they will produce similar values of \( \ln \mathcal{L} \), with differences far smaller than the differences between NR and model-based analysis.

For the reasons described in Section [IV.D] we consistently adopt SEOB-based models to evaluate our model-based \( \ln \mathcal{L} \). Because different phenomenological approximants do not agree, the posterior distributions used to identify the parameters for UID3 and 5 used an IMRD/P-based approximant produce different MaP and maxL parameters. Conversely, to the extent these models agree, they should estimate model parameters corresponding to the same values of \( \ln \mathcal{L} \). In fact, however, when we evaluate \( \ln \mathcal{L} \) with SEOBNRv4 on the MaP and maxL parameters of the posterior used to find UID5, we find both values disagree with the values seen for UID4, being lower (60.8) and higher (62) respectively. These differences in \( \ln \mathcal{L} \) clearly indicate small differences between the two model-based analyses, comparable to (but smaller than) the differences seen between model-based analyses and NR.
