Carbon dioxide (CO₂) is available in almost infinite amounts in our atmosphere and oceans, but its utilization as feedstock for the chemical industry is often prevented by its thermodynamic stability. Nevertheless, significant progress has been made in the utilization of CO₂ as a simple C₁ synthon for organic synthesis over the last years. Only however, a few large-scale industrial processes utilizing CO₂ as a simple feedstock for organic reactions have been achieved so far, such as the production of urea, methanol, salicylic acid, or cyclic carbonates.

Dioxolanes are useful intermediates to synthesize vicinal diols, which are industrially useful monomers, polymers, surfactants, plasticizers, cross-linking agents, curing agents, and solvents, to name a few applications only. The synthesis of organic carbonates by catalytic insertion of carbon dioxide into a carbon–oxygen bond of an epoxide usually requires the use of high temperature and pressure. Various catalysts for this reaction have been developed, including metal complexes [6–10] (e.g., metal–salen complexes and metalloporphyrins) and organocatalysts (e.g., quaternary ammonium salts or N-heterocyclic carbazenes). Among these catalysts, metalloporphyrins have shown relatively high catalytic activity under CO₂ autoclave conditions (>5 bar) and at elevated temperatures (usually >100 °C). In contrast to porphyrin-based systems, the closely related corrole macrocycle can stabilize metal ions in higher oxidation states, making them unique reagents with extraordinary catalytic properties. In this study, we focused on manganese, iron, cobalt, copper, antimony and bismuth 5,10,15-tris(pentafluorophenyl) corrole (MTpFPC) complexes 1a–f (Figure 1) for CO₂ fixation reactions. The center metal ions are complexed as Bi[13] Co[14] Cu[15] Fe[14,16] and Mn[14] accordingly, and the three C₆F₅₃ groups in the macrocycle withdraw electron density from the 18-ν-electron system. A consequence of this effect is the improved stability of such high-valent metal corroles. Nozaki and co-workers recently reported the use of Fe corroles and bis(triphenylphosphine)iminium chloride as an additive for the copolymerization of epoxides with CO₂ under high pressure conditions. Interestingly, in this case study, the formation of the cyclic carbonates was more or less totally suppressed. Based on our recent interest in the use of metal corroles as catalysts[17] and the recent progress in the use of cooperative CO₂-fixation catalyst systems based on metal complexes in combination with simple nucleophilic halide sources such as tetrabutylammonium bromide (TBAB),[18] we reasoned that the use of alternative metal-based corroles together with TBAB may result in a very powerful cooperative catalyst system for the CO₂ fixation with epoxides. Such a catalyst system may even operate under an atmospheric pressure of CO₂ at low temperature. Because of this lower CO₂ pressure, we argued that this synergistic catalyst combination may allow us to selectively access cyclic carbonates instead of polymerization products, which would thus result in a highly complementary...
Table 1. Identification of the optimum catalyst system for the CO₂ fixation of epoxide 2a.

| Entry [a] | 1 [mol%] | TBAB [mol%] | T [°C] | t [h] | Conv [%] |

[a] 4 mmol scale (neat); [b] judged by 1H NMR of the reaction mixture; [c] isolated yield after filtration over a short plug of silica; [d] based on 1a. TON = turnover number; TOF = turnover frequency.

approach to Nozaki’s impressive polymerization protocol[14] by relying on a similar corrole system.

Table 1 gives an overview of the most significant results obtained in a detailed screening of different metal corroles 1 in combination with TBAB as a cheap nuclophilic organic halide source for the solvent-free CO₂ fixation of styrene oxide (2a) under an atmosphere of CO₂ (using a balloon). As expected, only the synergistic combination of corroles 1 and TBAB allows for a reasonable conversion within a relatively short reaction time (at slightly elevated temperatures). In contrast, the absence of either 1 or TBAB resulted in no or only very slow formation of 3a only (entries 1–4). Testing of the different metal corroles 1a–f next showed that Mn- and Fe-based ones clearly outperformed the other metal complexes tested herein (entries 1 and 5–9). Owing to the superior catalytic performance of Mn-corrole 1a we further fine-tuned the reaction conditions with this system (entries 10–13). Hereby, it was found that reducing the catalyst loading below 0.01 mol% 1a resulted in a reduced conversion rate (entries 10 and 11). On the other hand, carrying out the reaction with 0.05 mol% 1a and 2 mol% TBAB (entry 12) leads to a higher conversion, and a slightly longer reaction time of 8 h results in almost full conversion of 2a under relatively mild conditions with low Mn-corrole loadings (entry 13).

Having identified the best-suited cooperative catalyst combination and reaction conditions for the solvent-free CO₂ fixation of epoxide 2a, we next investigated the scope of this protocol by using other simple epoxides 2 (Table 2). Most of the epoxides reacted at a similar rate to the parent styrenoxide 2a at 60 °C. Only the diphenylmethylether-based starting material (entry 6) and epichlorhydrine (entry 7) showed a slightly slower conversion of less than 90% under standard conditions. In contrast, some aliphatic epoxides even showed good conversion at room temperature (entries 10–12), thus proving the generality of this method for the CO₂ fixation with epoxides 2.

The synergistic effect of an organic nuclophilic halide source and a Lewis acidic metal complex for these CO₂-fixation reactions has been the subject of detailed recent mechanistic studies.[5,7,8] For example the groups of North et al. and Ren and Lu have done systematic investigations of salen- and salphen-based systems,[5,7] while Hasegawa et al. have carried out very detailed DFT investigations for porphyrin-based catalyst systems at elevated CO₂ pressure.[8] Based on these comprehensive studies we propose that the herein-reported Mn-corrole 1a/TBAB system operates through an analogous mechanism (Scheme 1). To corroborate the mechanism, we performed DFT calculations of the three main proposed intermediates A–C. The corrole macrocycle exhibits a cone-shaped structure after coordination with the ring-opened substrate (intermediate A) and the manganese atom lies slightly above the plane defined by the four nitrogen atoms of the corrole ring. The Mn atom is coordinated by the four nitrogen atoms and axially by the oxygen atom of the ring-opened epoxide. After the insertion reaction of CO₂, the axial pyramidal conformation is distorted (see structure B). Herein, one O atom originating from CO₂ is axially coordinating with a distance of 1.8 Å to the manganese ion, and the other oxygen atom is 2.86 Å apart from the Br methylene group and can easily perform, in the final step, the ring-closure to the cyclic carbonate 3.

To obtain further mechanistic details, we investigated the time course UV/Vis spectral changes occurring to the catalyst 1a during the reaction. The typical UV/Vis absorption spectrum of 1a and propylene oxide (Figure 2, solid black line) changes significantly after addition of TBAB under a CO₂ atmosphere (dotted green line, 2). While the Soret band maxi-

A and could be detected, still making it impossible to unambiguously assign the illustrated UV/Vis spectrum in Figure 2 (dotted green line, 2) to either intermediate A or B.

Finally, after full conversion of propylene oxide to carbonate 3 the UV/Vis absorption spectrum (Figure 2, dashed red line, 3) changes back, comparably to the one observed in the beginning for the non-reacted catalyst species 1a (Figure S3).

After recycling the manganese corrole species (column chromatography of the reaction mixtures first with heptanes/ETOAe = 10:1–3:1 to isolate the carbonates and then with heptanes/ETOAe = 1:1 to elute the catalyst), analysis of ESI-MS and 19F NMR spectra (Figures S4 and S5) revealed that the manganese corrole remained intact and was reusable for further transformations.

To conclude, we have identified that TBAB/MnIII-corrole 1a is the best-suited cooperative catalyst combination so far. Owing to the superior catalytic performance of Mn-corrole 1a we further fine-tuned the reaction conditions with this system. Hereby, it was found that reducing the catalyst loading below 0.01 mol% 1a resulted in a reduced conversion rate. On the other hand, carrying out the reaction with 0.05 mol% 1a and 2 mol% TBAB led to an increased conversion, and finally a slightly longer reaction time (8 h) results in > 95% conversion of 2 under relatively mild conditions with low Mn-corrole loadings.

The dramatic changes observed in the time course UV/Vis spectra for 1a during the reaction could be attributed to the effect of axial binding of the oxygen atom of the ring-opened epoxide, and to the intermediate B after CO2 insertion/fixation. Finally, we have shown that recycling of the Mn-corrole is possible and makes the Lewis-acidic manganese corrole complex reusable for further transformations.
