Abstract

Background: Haemorrhagic fever with renal syndrome (HFRS) is characterised by an uncontrolled cytokine storm that causes vascular leakage and kidney injury. The cytokine interleukin 34 (IL-34) enhances proliferation and differentiation of myeloid cells and secretion of pro-inflammatory cytokines, which is involved in the pathogenesis of some inflammatory and infectious diseases. However, to date, the role of IL-34 in patients with HFRS is unclear. This study aims to detect the plasma IL-34 levels of HFRS patients and discuss the possible effects of IL-34 in the pathogenesis of HFRS. Methods: IL-34 levels in the plasmas from 52 HFRS patients and 20 healthy controls were quantified using enzyme-linked immunosorbent assay. Results: Compared with healthy controls, the plasma IL-34 levels in HFRS patients were significantly elevated at acute phase 37.92 (10.58-73.86) pg/ml vs. 7.13 (3.99-11.31) pg/ml, p < 0.0001 and then decreased to the normal levels at convalescent phase. Importantly, IL-34 levels positively correlated with white blood cell count and monocyte count (r = 0.503, p < 0.0001 and r = 0.367, p = 0.0003, respectively), and negatively correlated with platelet count and serum albumin levels (r = -0.614, p < 0.0001 and r = -0.598, p = 0.0003, respectively). Conclusions: IL-34 levels in plasma of HFRS patients were significantly elevated at acute phase and correlated with disease severity-reflecting parameters, which suggests a potential role of IL-34 in the pathogenesis of HFRS and should be future explore.

Background

Haemorrhagic fever with renal syndrome (HFRS) caused by Hantaan virus (HTNV) is a serious acute infectious disease distributed globally with great harm to human[1]. China is one of the most severe endemic areas of HFRS in the world, and accounts for almost 90% of human cases globally with the highest incidence each year[2, 3]. Patients with HFRS is
pathological characterised by increased vascular endothelial permeability, thrombocytopenia and acute kidney injury (AKI)[4]. HTNV infection induced activation of immune system leading uncontrolled cytokine storm, such as dramatically increased cytokines interleukin 1 (IL-1), IL-6, chemokine (C-C motif) ligand 2 (CCL2), CCL4 and tumour necrosis factor-α (TNF-α)[4, 5]. These cytokines could feedback to enhance the function of immune system against HTNV infection, but also induce the reorganization of the endothelial cytoskeleton and junctions, which mediate an increase in endothelial permeability [6, 7]. Increased endothelial permeability leads to the dysfunction of vascular endothelial barrier, and manifested as petechiae, oedema, and hypotension[8]. The cytokine storm caused dysfunction of vascular endothelial barrier may underlie one of the pathogenesis of HFRS. Additionally, pro-inflammatory cytokines as endogenous pyrogen could induce fever, which is the early clinical manifestation of HFRS[9]. Patients with HFRS showed increased thrombopoiesis and platelet activation, which may induce intravascular coagulation and cause the thrombocytopenia[10, 11]. Moreover, the infiltration of inflammatory cells and pro-inflammatory cytokines in kidney tissue could lead to kidney damage[4].

IL-34 is a 39 kDa glycoprotein belonging to the short chain α-helix cytokine family. IL-34 could be secreted by multiple cell types, such as neurons, keratinocytes, synovial fibroblasts, osteoblasts, cytotoxic T cells, plasmacytoid dendritic cells, and adipocytes[12-16]. Three kinds of receptors for IL-34 have been identified, including CD115 (colony stimulating factor 1 receptor, CSF-1R; macrophage colony-stimulating factor receptor, M-CSFR), the receptor-type protein-tyrosine phosphatase zeta (PTP-ζ) and CD138 (syndecan-1). CD115 is primarily expressed on monocyte precursors, monocytes, dendritic cells and tissue macrophages[17]. Physiologically, expression of IL-34 is restricted to epidermis and central nervous system, which could regulate differentiation of myeloid cells to
Langerhans cells and microglia, and modulate their function by binding with CD115 [18, 19]. PTP-ζ is primarily expressed on neural progenitors and glial cells, especially highly expressed in human glioblastomas. The action of IL-34 and PTP-ζ could inhibit the proliferation, clonogenicity and metastasis of these cancer cells[12, 20]. Furthermore, it is found later that IL-34 could bind to chondroitin sulphate chains of CD138, and modulates IL-34-induced CSF-1R activation and affects cellular migration[21]. Importantly, the expression of IL-34 could be enhanced by pro-inflammatory cytokines TNF-α and IL-1β, which is mainly driven by infection and/or inflammation[15, 22, 23], whereas the production of IL-34 could be inhibited by interferon γ (IFN-γ)[bone morphogenetic protein 2 (BMP-2) and transforming growth factor β1 (TGF-β1)[24, 25]. IL-34 is involved in inflammatory diseases accompanied by monocytes/macrophages over-proliferation and virus infectious diseases, such as inflammatory bowel disease (IBD)[16], Sjögren's syndrome (SS)[26], hepatitis C virus (HCV)[15] and equine infectious anemia virus (EIAV) infection[27]. These studies showed the potential role of IL-34 as a novel diagnostic and prognostic biomarker of these diseases. Our previous studies have found that blood monocytes were significantly increased in patients with HFRS caused by HTNV infection[28]. However, the change and the role of IL-34 during HTNV infection remains largely unknown. Hence, investigating the changes in the levels of IL-34 and the effect of IL-34 on the pathogenesis of HFRS is an important avenue of study.

In this study, we detected the levels of IL-34 in the plasma of patients with HFRS, and found that IL-34 were significantly increased at the acute phase of HFRS. Importantly, the levels of IL-34 correlated with the typical clinical parameters reflecting disease severity of HFRS, which suggested that IL-34 may play an important role after HTNV infection in patients with HFRS.

Methods
Study design

We performed a case-control study. Cases were defined as patients with HFRS. The clinical diagnosis of HFRS was serologically confirmed by detecting specific IgM and IgG antibodies to HTNV. According to the diagnostic criteria from the Prevention and Treatment Strategy of HFRS promulgated by the Ministry of Health, the People’s Republic of China, patients with HFRS were classified into four clinical types: mild, moderate, severe, and critical [29, 30].

1. **Mild**: mild kidney damage with proteinuria ranging from “+” to “++” and no obvious oliguric period;
2. **Moderate**: obvious symptoms of effusion (bulbar conjunctiva), uraemia, haemorrhage (skin and mucous membrane), and kidney damage with “+++” urinary protein and occurrence of significant oliguric period;
3. **Severe**: severe effusion (bulbar conjunctiva and either pleura or peritoneum), uraemia, haemorrhage (skin and mucous membrane), and kidney damage with oliguria (urine output, 50-500 mL/day) for ≤ 5 days or anuria (urine output, < 50 mL/day) for ≤ 2 days;
4. **Critical**: ≥ 1 of the following symptoms during severe disease: visceral haemorrhage, refractory shock, heart failure, pulmonary oedema, brain oedema, severe secondary infection, and severe kidney damage with oliguria (urine output, 50-500 mL/day) for > 5 days, anuria (urine output, < 50 mL/day) for > 2 days, or a blood urea nitrogen level of > 42.84 mmol/L.

According to the clinical observation, HFRS is defined by five sequential stages: febrile, hypotensive, oliguric, diuretic, and convalescent. These stages are usually classified as the acute phase (febrile, hypotensive, and oliguric stages) and the convalescent phase (diuretic and convalescent stages) [31]. In general, samples were collected at 3–6 days for the febrile or hypotension stage, 7–12 days for the oliguric stage, after 13–18 days for the diuretic stage and after 18 days for the convalescent stage.

Patients with other kidney diseases, diabetes, haematological diseases, cardiovascular
diseases, autoimmune diseases, viral hepatitis, and other inflammatory diseases were excluded from this study.

Shaanxi Province, an administrative province in northwestern China, is the most serious HFRS endemic areas of China[2]. Blood samples were intravenously collected from 52 hospitalised HFRS patients between 2015 and 2017 at the Tangdu Hospital of the Fourth Military Medical University (Xi’an, Shaanxi Province, China) and from 20 healthy donors (normal controls, NC). The plasma samples were isolated from EDTA (anticoagulant)-treated blood samples by centrifugation and cryopreserved at −80°C before analysis.

Enzyme-Linked immunosorbent assay for the detection of IL-34 levels in plasma

The IL-34 levels in plasma were measured using the sandwich enzyme-linked immunosorbent assay (ELISA) kit (R&D systems, D3400), according to the manual. A monoclonal antibody specific for human IL-34 has been pre-coated onto a microplate. Standards and samples were pipetted into the wells, and any IL-34 present in sample was bound by the immobilized antibody. After washing away any unbound substances, the horse radish peroxidase (HRP)-linked monoclonal antibody for human IL-34 was added to the wells. Then substrate solution Tetramethylbenzidine (TMB) was added to the wells for detection after washing unbound enzyme-linked monoclonal antibody, and stopped by sulfuric acid. Optical densities were determined at 450 nm with a 570 nm wavelength correction.

Statistical Analysis

The statistical analysis was performed in the GraphPad Prism6 software. The comparison between different groups were determined by the Mann–Whitney U test. The continuous variables were presented as medians with their corresponding interquartile ranges (IQRs).
The nonparametric Spearman correlation test was used for correlation analysis of IL-34 levels in the plasma with clinical parameters. $p$-values (two-tailed) below 0.05 were considered statistically significant.

Results

A total of 50 acute-phase plasma and 45 convalescent-phase plasma samples from 52 patients (male/female, 44/8) with HFRS were examined. Meanwhile, 20 plasma samples from 20 healthy donors were assessed in this study. There were 1 mild, 11 moderate, 16 severe, and 24 critical HFRS patients, respectively. The median of age with IQR was 45 (17-82) years for HFRS patients. Furthermore, clinical parameters of all enrolled subjects were summarized in Table 1.

Considering the different phases of HFRS, the IL-34 levels in plasma were 5.3-fold higher at the acute phase compared with the normal controls [37.92 (10.58-73.86) pg/ml vs. 7.13 (3.99-11.31) pg/ml, $p < 0.0001$], and these levels decreased at the convalescent phase [4.66 (2.63-9.77) pg/ml, $p < 0.0001$] (Fig. 1A). There was no significant difference of IL-34 levels in plasma between HFRS patients at convalescent phase and normal controls ($p > 0.05$). The dynamic changes of plasma IL-34 levels in the same individual also showed the same tendency, that IL-34 levels in plasma were elevated at acute phase and recovered to the normal levels at convalescent phase (Fig. 1B). Between the different HFRS severity groups, there were no significant differences in the plasma IL-34 levels (data not shown).

Further, the relationships were analyzed between plasma IL-34 levels and the clinical parameters detected during hospitalization. Each value of clinical parameters was derived from the same sample. The IL-34 levels in the plasma of HFRS patients positively correlated with white blood cell count (WBC) ($r = 0.503$, $p < 0.0001$, Fig. 2A) and monocyte count (MONO) ($r = 0.367$, $p = 0.0003$, Fig. 2B), and negatively correlated with the platelet count (PLT) ($r = -0.614$, $p < 0.0001$, Fig. 2C) and serum albumin (ALB) levels.
Discussion

Our study firstly found that the IL-34 levels in plasma of HFRS patients were significantly elevated at acute phase, and decreased to the normal levels at convalescent phase. Importantly, the IL-34 levels correlated with clinical parameters WBC, MONO, PLT and ALB, which could reflect the severity of the disease, suggesting that IL-34 may play an important role in the pathogenesis of HFRS. Pro-inflammatory cytokines TNF-α and/or IL-1β stimulation could enhance the IL-34 expression of immune cells such as cytotoxic T cells, plasma cells, monocytes/macrophages and plasmacytoid dendritic cells, and tissue cells such as vascular endothelial cells, fibroblast-like synovial cells, osteoblasts and adipocytes[14, 15, 32]. At the acute phase of HFRS patients, levels of TNF-α and IL-1β in serum were significantly elevated [5], which may increase the secretion of IL-34 from above immune cells and tissue cells and contribute to the elevation of plasma IL-34 levels. In our previous study, we found that level of plasma adiponectin, which is predominantly secreted by adipocytes, was significantly elevated in HFRS, suggesting that systemic inflammatory response influenced the function of adipocytes in patients with HFRS[33]. The systemic inflammatory response during HTNV infection may also promote the secretion of IL-34 by adipocytes. WBC was increased significantly in HFRS patients. We found that plasma IL-34 levels positively correlated with WBC, which implied that increased WBCs under pro-inflammatory cytokines stimulation may produce higher level of IL-34 in plasma.

IL-34 is recently described as a pro-inflammatory cytokine by promoting myeloid lineage differentiation, proliferation, and survival and also by inducing secretion of pro-inflammatory cytokines and chemokines such as IL-6, IL-8 and CCL2 in human whole
blood[17, 34, 35]. MONO was increased significantly in HFRS patients. We showed that plasma IL-34 levels positively correlated with MONO. Increased IL-34 may act on monocytes and promote their proliferation and survival, leading the accumulation of monocytes in the circulation blood. Importantly, Ciccia et al. have found that increased IL-34 levels of patients with SS were associated with local expansion of CD14++CD16+ monocytes, and IL-34 could induce the expansion of both CD14++CD16− and CD14++CD16+ monocytes in vitro[36]. We also found that CD14++CD16− and CD14++CD16+ monocytes were remarkably increased in the blood of HFRS patients at the acute phase in our previous study[28]. Therefore, we speculated that the increased plasma IL-34 may contribute to the expansion of blood CD14++CD16− and CD14++CD16+ monocytes in HFRS patients. Interestingly, blocking IL-34 by specific monoclonal antibody could be an effective therapy for myeloid driven inflammatory disease in mice[37], which may provide a new strategy for the therapy of HFRS by inhibit IL-34 induced inflammation.

It has been found that IL-34 could incite the expression of chemokines, such as CCL2 that recruit monocytes into kidney tissues, which aggravates AKI and leads subsequent chronic kidney disease (CKD). The time-related magnitude of macrophage-mediated AKI and subsequent CKD were markedly reduced in IL-34–deficient mice compared with controls. Based on these findings, targeting IL-34 is likely a potential therapeutic strategy to suppress AKI and CKD[38-40]. Dysfunction of glomerular basement membrane during AKI could influence the selective exclusion of ALB from the glomerular filtrate leading to ALB loss in the urine[41]. At the acute phase of HFRS patients, the serum ALB levels were decreased for the injury of kidney function. Here, we found that plasma IL-34 levels negatively correlated with serum ALB levels, suggesting the IL-34 may be involved in the dysfunction of kidney of HFRS patients. Thrombocytopenia induces coagulation disorders
and the hemorrhage of HFRS patients. IL-34 levels negatively correlated with PLT, suggesting IL-34 may participated in the decrease of blood platelet during HTNV infection by a complex network.

S2 protein of EIAV specifically induces the expression of IL-34 and may optimize the host macrophage environment to favor viral dissemination and replication, which have a major impact in EIAV induced pathogenesis and disease progression[27]. IL-34 treated macrophages showed slightly higher levels of mitogen-activated protein kinase (MAPK) phosphorylation and associated with higher replication of HIV-1[42]. Interestingly, IL-34 treated macrophages could inhibit IFN-γ production by NK cells, while IFN-γ could inhibit IL-34 expression[14, 15, 24, 25]. IL-34 and IFN-γ-mediated pathways seemed to be antagonistic. Therefore, IL-34 stimulation may benefit for the replication of viruses. In the acute phase of HFRS patients, we found that HTNV load were significantly higher in patients with severer disease severity[43]. Other studies also showed the dysfunction of IFN-γ secreting by host immune cells during HTNV infection[44]. The increased plasma IL-34 levels at the acute phase of HFRS patients may contribute to the replication of HTNV and the pathogenesis of HFRS.

Conclusions

IL-34 could be as a biomarker that help to evaluate inflammatory disease progression and a potential therapeutic target for controlling infections and inflammation. We have found that the IL-34 levels in plasma of patients with HFRS were significantly elevated at acute phase and correlated with clinical parameters reflecting the disease severity, which suggests a potential role of IL-34 in the pathogenesis of HFRS and should be future explore.

Tables

Table 1: Clinical parameters of HFRS patients in this study.

| Clinical parameters               | Acute phase       | Convalescent phase |
|----------------------------------|-------------------|--------------------|
| White blood cell count (×109/L)  | 15.42 (9.61-23.19)| 8.12 (6.35-10.05)  |
| Blood platelet count (×109/L)    | 44.00 (26.50-80.50)| 196.00 (122.50-278.00)|
| Monocyte count (×109/L)          | 1.25 (0.86-2.24)  | 0.78 (0.53-1.24)   |
| Blood urea nitrogen level (mmol/L) | 15.67 (9.10-22.23) | 12.30 (6.90-18.50) |
| Serum creatinine level (µmol/L)  | 297.50 (128.80-483.60)| 211.90 (126.40-340.70)|
| Serum albumin level (g/L)        | 26.90 (25.60-29.35)| 37.40 (31.50-41.35)|

Values represent medians with the corresponding interquartile range (IQR).

Figures
Dynamic changes of interleukin 34 (IL-34) levels in the plasma of patients with HFRS. (A) A comparison of IL-34 levels in plasma among the acute and convalescent phases of HFRS patients and normal controls (NC). (B) Changes in the levels of IL-34 in the plasma of the same individuals were shown. The Mann-Whitney U test was used to determine the significance of the difference between two groups, and the black lines represent the medians with the corresponding interquartile range. p-values below 0.05 were considered statistically significant.

****p<0.0001.

Correlations between the IL-34 levels in plasma and clinical parameters of HFRS patients. Correlation of IL-34 levels in the plasma of HFRS patients with (A) white blood count (WBC), (B) monocyte count (MONO) (C) platelet count (PLT), and (D) serum albumin (ALB) levels were evaluated using the nonparametric Spearman correlation test. Each value of clinical parameters was derived from the same sample. The r denotes the Spearman correlation coefficient. p-values below 0.05 were considered statistically significant.
