Research article

Keywords: depressive, postnatal, pregnant, quality of life, women
Abstract

Background: This study examined the prevalence of depressive symptoms (depression hereafter) and its association with quality of life (QOL) among pregnant and postnatal women in China.

Methods: In this multicenter, cross-sectional study, 1,060 pregnant and postnatal women from eight hospitals were assessed. Depression and QOL were measured using standardized instruments.

Results: The prevalence of depression was 7.45% (95%CI: 5.87%-9.04%) in the sample. Women with depression had lower QOL in physical, psychological, social and environmental domains compared to those without. Women with physical comorbidities were more likely to suffer from depression (OR=2.391, 95%CI=1.384-4.130, P=0.002).

Conclusion: Due to its negative association with QOL, increased attention should be paid to depression in pregnant and postnatal women. Regular screening assessment and preventive measures should be adopted to reduce risk of depression in this population.

Introduction

Pregnancy is characterized by multiple hormonal and anatomical changes that are associated with high risk of mental health problems such as irritability, sleep disturbances, depression and even suicidality [1, 2]. Studies have found that depressive symptoms (referred to as depression hereafter) are more prevalent among pregnant and postnatal women than women with physical problems such as preeclampsia, preterm childbirth and gestational diabetes [3]. However, depression during pregnancy and the postnatal period has often been unrecognized by clinicians because it has parallels with certain pregnancy symptoms such as loss of appetite and energy, tiredness, and libido changes [4].

In order to reduce the risk of depression during pregnancy and the postnatal period and its negative impact on health outcomes, researchers should examine its epidemiology and correlates. A meta-analysis revealed that the overall prevalence of depression in pregnant and postnatal women was 11.9% (95% CI: 11.4%-12.5%) [5]. Another meta-analysis revealed that the overall prevalence of postpartum depression among healthy mothers was 17% (95% CI: 15–20%) [6]. A range of demographic and socio-demographic factors are associated with depression during pregnancy and the postnatal phase. For instance, researchers have found that older age, lower socioeconomic status, poorer relationships with family, intimate partner violence and unplanned pregnancy are risk factors for depression among pregnant and postnatal women [3, 7–9], while comfortable living conditions, psychological resilience, and better social support perceived by women predict reduced risk for depression [10]. In addition, sociocultural and economic contexts have significant associations with depression during pregnancy and following childbirth [7, 8]. Therefore, its prevalence and correlates should be examined separately in different countries.

In China, some studies on depression in the perinatal period have been conducted, but findings have varied significantly, in part, because of sample differences in demographic characteristics, measurement tools, and recruitment procedures. A China-based meta-analysis revealed that the prevalence of depression during the perinatal period was 17.4% [11], but the rate decreased to 10.7% among postpartum women [12]. Common limitations of previous studies conducted in China include the reliance on single study sites, small sample sizes, and univariate rather than multivariate analyses as well as the failure to use specific measures on perinatal depression such as the Edinburgh Postnatal Depression Scale (EPDS) [11, 12]. Instead, most previous studies used generic measures of depression such as the Patient Health Questionnaire (PHQ9), Zung Self-Rating Depression Scale (SDS), and Beck Depression Inventory (BDI), all of which are less appropriate because normal postnatal experiences reflecting changes in appetite and sleep as well as loss of energy can be misconstrued as depressive symptoms on generic scales.

For several decades, quality of life (QOL) has been widely used as a comprehensive health outcome in clinical practice and research. For pregnant and postnatal women, the focus of QOL has expanded from preventing, detecting, and managing problems or complications to ‘supporting psychological adaptation to pregnancy’ [13]. Most past studies only examined QOL in pregnant and postnatal women with physical diseases such as gestational diabetes, and hypertension [14, 15]. In contrast, little
is known about the association between QOL and depression in general samples of pregnant and postnatal women. Thus, we conducted this study to examine the prevalence of depression, and its demographic and clinical correlates and association with QOL among pregnant and postnatal Chinese women.

Methods

Study settings and participants

This was a multicenter, cross-sectional study conducted between February and October, 2019. Eight major hospitals in Beijing, Xinjiang, Liaoning, Guangdong, Qinghai, Hubei, Jiangsu and Sichuan provinces that are located in central, northern, southern, eastern, and western China were included to represent a range of major geographic regions in China to reduce sampling biases related to single site research and increase the sample representativeness. A consecutive patient sampling method was adopted. All women treated in Department of Obstetrics of the participating hospitals at daytime during the study period were included in this study if they met the following inclusion criteria: 1) age 18 years or older; 2) comprehension of spoken Chinese language; 3) current pregnancy or postnatal status (i.e., from the beginning of pregnancy to 1 week after delivery); 4) provision of written informed consent. Participants were excluded if they had pre-existing psychiatric disorders such as major depressive disorder, or disturbances of consciousness that can interfere with comprehension of research measures.

Assessment instruments and study procedure

Basic demographic information, including maternal age, height (m), weight (kg), education level, marital status, employment status, gestation, personal monthly income, history of miscarriage, placenta abruption, and physical comorbidities, were assessed on a background information form. The 10-item self-report Edinburgh Postnatal Depression Scale (EPDS) – Chinese version [16] was used to assess severity of depressive symptoms in the past week during pregnancy or the postnatal period. Total scores ranged from 0 to 30, with higher scores indicating more severe depression. An EPDS total score of 13 or above indicates ‘having depression’ [16]. The Chinese version of EPDS had excellent psychometric properties [17]. The World Health Organization Quality of Life Questionnaire – brief version (WHOQOL-BREF) was used to assess QOL. The WHOQOL-BREF consists of 26 items, covering physical, psychological, environmental and social QOL [18]. A higher total score indicates better QOL [19]. The Chinese version of this scale has good psychometric properties [20].

Following other studies [21, 22], three standardized ‘Yes/No’ questions were utilized to evaluate suicidal behaviors in the past year, including 1) suicidal ideation (SI) – ‘Have you ever thought about killing yourself?’, 2) Suicide plans (SP) – ‘Have you ever made a plan for committing suicide, or even taken steps to prepare for this plan?’, and 3) Suicide attempts (SA) – ‘Have you ever attempted suicide?’. Participants who answered ‘Yes’ to any of the three questions were considered as ‘having suicidality’.

All participants were approached by trained nurses who explained the study aim and procedure. For those who agreed to participate and provided written informed consent form, a face-to-face interview was conducted. This study was approved by the Clinical Research Ethics Committee of the Peking Union Medical College Hospital and all participating hospitals (Ref No: S-K1273). All the study procedures were carried out in accordance with relevant guidelines.

Sample size estimation

The total sample size of participants was estimated using a standardized formula: \( N = Z_\alpha^2 P (1 - P) / d^2 \) [23]. N means the sample size, Z means the statistic of significance test, alpha means the significance level, P means the prevalence, and d means the allowable error. In this study, alpha was set at 0.05, \( Z_\alpha = 1.96 \), and the estimated acceptable margin of effort for proportion \( d \) was 0.1 as recommended [23]. The prevalence of depression in pregnant and postnatal women was 15% in a systematic review [24], which was used for sample size calculation in this study. A minimum sample size of 490 participants were needed. To increase the statistical power, we recruited 1,100 participants in this study.

Statistical analyses
Data analyses were performed using SPSS V24.0. Normality distributions of continuous variables were checked by one-sample Kolmogorov-Smirnov tests. Differences on demographic and clinical characteristics between depression and no depression groups were assessed using independent samples t-tests for normally distributed continuous variables, Mann-Whitney U tests for non-normally distributed continuous variables, and Chi-square tests/Fisher exact tests for categorical variables. Analysis of covariance (ANCOVA) was used to compare QOL between depression and no depression groups after controlling for variables on which these groups differed (P < 0.05) in univariate analyses. Binary logistic regression analysis based on the “enter” method was used to examine independent correlates of depression. Depression was the dependent variable, while variables on which there were significant univariate group differences were entered as independent variables. Significance was set at P < 0.05, with two-tailed tests.

Results

A total of 1,140 women were invited to participate in this study; of these, 1,060 agreed and completed the assessment, producing a response rate of 92.98%. The overall prevalence of depression was 7.45% (95%CI: 5.87%-9.04%); within the depressed subgroup (N = 79), the highest rate was found in the third trimester (45.6%), followed by the first trimester (25.3%) and second trimester (19.0%). The lowest figure was shown among postnatal women (10.1%). Within the entire sample, 27 (2.6%) women reported having experiences of suicidality, with 26 (2.5%) reporting suicidal ideation, 4 (0.38%) reporting a suicide plan and 5 (0.47%) admitting to a suicide attempt. Specifically, there were 14 women (17.7%) with suicidality in the depression group compared to 13 women (1.3%) in the no depression group (P< 0.001). Demographic and clinical characteristics are presented in Table 1.

Note: a: Fisher’s Exact Test; b: using age, abortion by drugs, and comorbidity as covariates; c: using age, natural miscarriage, and comorbidity as covariates; d: using age, natural miscarriage, and abortion by drugs as covariates; e: using natural miscarriage, abortion by drugs, and comorbidity as covariates; BMI = Body mass index; CI = Confident Interval; EPDS = Edinburgh Postnatal Depression Scale; QOL = Quality of life;

In univariate analyses, depression was significantly associated with previous natural miscarriage experiences ($P=0.041$), drug-induced abortion history ($P=0.025$) and physical comorbidities ($P=0.001$) which were controlled for as covariates in subsequent analyses. Women with depression had lower physical, psychological, social and environmental quality of life compared to those without (all $P$ values $<0.001$) after controlling for covariates. A multivariate logistic regression analysis revealed that women with physical comorbidities were more likely to suffer from depression (OR $=2.391$, 95%CI $=1.384–4.130$, $P=0.002$) (Table 1).

**Discussion**

Due to hormonal and anatomical changes and other factors including heavier care burdens, pregnant and postnatal women are more likely to suffer from psychological disturbances, particularly depression [25]. In this study, the prevalence of depression was 7.45% (95%CI: 5.87–9.04%) among pregnant and postpartum women, a rate that was lower than estimates from recent China-based meta-analyses [11, 12]. Notably, however, rates have varied between reviews. For example, an older meta-analysis [26] found that the pooled point prevalence of perinatal depression ranged from 6.5–12.9% from the start of pregnancy to the first postpartum year; 19.2% of the depressed subgroup reported depression during the first 3 months after delivery. Conversely, another recent meta-analysis found the overall prevalence of depression in pregnant and postnatal women was 11.9% (95% CI: 11.4%-12.5%) [5]. Discrepant rates between studies could be partly explained by different study samples, sampling methods, sample sizes, measurement tools for depression, socioeconomic backgrounds and clinical status [5, 6, 26].

Previous studies have indicated that depression is a strong predictor of suicidality [27–29]. In this study, a relatively small proportion of women reported suicidal ideation (2.5%), plan (0.38%) or attempt (0.47%) but the rate was substantially higher than those of other studies. For example, a large retrospective study from the US found that the prevalence of suicide attempts during pregnancy was 0.04% [30]. Another study from Canada reported that the prevalence of suicide attempts was 0.03% in pregnant women and 0.06% in postnatal women [31]. A study conducted in mainland China found that the prevalence of suicide attempt during pregnancy was 0.21% [32]. Reasons for the comparatively higher rate in this research are not known. However, due to differences in timeframes and measures of suicidality between studies, direct comparisons should be made with caution. The growing awareness of mental health concerns in pregnant and postnatal women, better social support networks, increased stigma related to disclosing distress, and accessibility to mental health services in major cities of China where the participating hospitals are located could contribute to the low overall prevalence of suicidality in this population.
Nonetheless, we found that pregnant and postnatal women with depression were more likely to have suicidality compared with those without, which is consistent with previous findings [1, 33].

Additionally, our study found that participants with physical comorbidities were more likely to report depression, which also dovetails with previous findings [34, 35]. Physical comorbidities and adverse effects of treatments in pregnant and postnatal women were associated with more severe physical discomfort and impaired daily functioning, which could increase the risk of depression [34, 35].

Similar to previous findings [36], depression was significantly associated with lower QOL in all domains. The poorer QOL of depressed women could be explained by the distress/protection QOL model, in which QOL is determined by a range of protective and distressing factors [37]. QOL tends to be lower if distressing factors (e.g., frequent sleep disturbances, fatigue, and physical discomfort caused by depression) predominate over protective factors (e.g., better social support from social networks). Depressed women often present with psychological and physical symptoms such as sadness, helplessness, cognitive impairments, body pain, insomnia, and digestive problems [38], all of which are related to lower QOL in depressed pregnant and postnatal women.

The merits of this study included its multicenter study design, large sample size, and use of a depression measure validated specifically for pregnant and postnatal depression. The main limitations should also be acknowledged. First, this was a cross-sectional study, so causal associations and changes between variables over time could not be examined. Second, all results were based on self-reported data; therefore, we cannot rule out biases in recall or social desirability as influences on the data. Third, to ensure response burdens were not excessive, variables that may be related to depression, such as social support, were not included in this study. Fourth, although a relatively large sample size and multicenter design based on different geographic regions of China were used, the needed number of eligible perinatal women was not calculated separately for each participating hospital. In addition, those with pre-existing psychiatric disorders and potential comprehension difficulties were excluded. Therefore, selection biases cannot be ruled out as influences on the data. To increase population representativeness, more costly national epidemiological surveys using multistage designs and random sampling should be conducted in China.

**Conclusion**

In conclusion, due to the significant associations of depression with suicidality, and lower QOL, increased attention should be paid to pregnant and postnatal women. Preventive measures, such as regular assessment and management of physical comorbidities, should be adopted to track and reduce risk of depression in this population. Timely treatment should be provided for women who experience depression during pregnancy and the postnatal period.
