Abstract

Background: A large amount of computational and experimental work has been devoted to uncovering network motifs in gene regulatory networks. The leading hypothesis is that evolutionary processes independently selected recurrent architectural relationships among regulators and target genes (motifs) to produce characteristic expression patterns of its members. However, even with the same architecture, the genes may still be differentially expressed. Therefore, to define fully the expression of a group of genes, the strength of the connections in a network motif must be specified, and the cis-promoter features that participate in the regulation must be determined.

Results: We have developed a model-based approach to analyze proteobacterial genomes for promoter features that is specifically designed to account for the variability in sequence, location and topology intrinsic to differential gene expression. We provide methods for annotating regulatory regions by detecting their subjacent cis-features. This includes identifying binding sites for a transcriptional regulator, distinguishing between activation and repression sites, direct and reverse orientation, and among sequences that weakly reflect a particular pattern; binding sites for the RNA polymerase, characterizing different classes, and locations relative to the transcription factor binding sites; the presence of riboswitches in the 5'UTR, and for other transcription factors.

We applied our approach to characterize network motifs controlled by the PhoP/PhoQ regulatory system of Escherichia coli and Salmonella enterica serovar Typhimurium. We identified key features that enable the PhoP protein to control its target genes, and distinct features may produce different expression patterns even within the same network motif.

Conclusion: Global transcriptional regulators control multiple promoters by a variety of network motifs. This is clearly the case for the regulatory protein PhoP. In this work, we studied this
regulatory protein and demonstrated that understanding gene expression does not only require identifying a set of connexions or network motif, but also the cis-acting elements participating in each of these connexions.

Background
Transcription regulatory networks can be represented as directed graphs in which a node stands for a gene (or an operon in the case of bacteria) and an edge symbolizes a direct transcriptional interaction. Recurrent patterns of interactions, termed network motifs, occur far more often than in randomized networks, forming elementary building blocks that carry out key functions. This is a convenient representation of the architecture of a set of regulatory Boolean (i.e. ON-OFF) networks, in which each gene is either fully expressed or not expressed at all, or that it has a binding site for a transcriptional regulator or lacks such a site. However, this approach has serious limitations because most genes are not expressed in a simple Boolean fashion. Indeed, genes that are co-regulated by the same transcription factor are often differently expressed with characteristic expression levels and kinetics. Therefore, a deeper understanding of regulatory networks demands the identification of the key features used by a transcriptional regulator to differentially control genes that display distinct behaviours despite belonging to networks with identical motifs.

The identification of the promoter features that determine the distinct expression behavior of co-regulated genes is a challenging task because: first, these features are often short combinations of a constrained four-symbol DNA alphabet. Therefore, it is not clear how to distinguish a sequence pattern that could affect gene expression from a just slightly different random sequence [1,2]. Second, the sequences recognized by a transcription factor may differ from promoter to promoter within and between genomes and may be located at various distances from other cis-acting features in different promoters [3,4]. Third, similar expression patterns can be generated from different or a mixture of multiple underlying features, thus, making it more difficult to discern the causes of analogous regulatory effects.

In this study, we present a method specifically aimed at handling the variability in sequence, location and topology that characterize gene transcription. We decompose a feature into a family of models or building blocks that uncover important differences among observations that are often concealed when using global patterns that tend to average sequences between promoters and even across species. This approach maximizes the sensitivity of detecting those instances that weakly resemble a consensus (e.g., binding site sequences) without decreasing the specificity. In addition, features are considered using fuzzy assignments, which allow us to encode how well a particular sequence matches each of the multiple models for a given promoter feature. Individual features can be linked into more informative composite models that can be used to explain the kinetic expression behavior of genes.

We applied our method to analyze promoters controlled by the PhoP/PhoQ regulatory system of Escherichia coli and Salmonella enterica serovar Typhimurium. This system responds to the same inducing signal (i.e. low Mg\(^2+\)) in both species [4-7]. Moreover, the E. coli phoP gene could complement a Salmonella phoP mutant [8]. The DNA-binding PhoP protein appears to recognize a tandem repeat sequence separated by 5 bp [4-6], consistent with being a dimer [9]. The PhoP/PhoQ system is an excellent test case because it controls the expression of a large number of genes, amounting to ca. 3% of the genes in the case of Salmonella [10]. Furthermore, the PhoP/PhoQ regulon has been shown to employ a variety of network motifs including the single-input module (Fig. 1A), the multi-input module (Fig. 1B), the bi-fan (Fig. 1C), the chained (Fig. 1D), and the feedforward loop (Fig. 1E) [10-12]. Our analysis uncovered the salient features that distinguish genes co-regulated by PhoP belonging to similar networks. Gene transcription measurements provided experimental support for the investigated predictions.

Results and discussion
Approach
We investigated five types of cis-acting promoter features by extracting the maximal amount of useful information from datasets and then creating models that describe promoter regulatory regions. This entailed applying three key strategies: first, we conducted an initial survey of the data provided from different available sources, capturing and distinguishing between broad and easily discernable patterns. We then used these patterns as models to re-visit the data with greater sensitivity and specificity. This allowed us not only to recognize those instances with a low resemblance to consensus models, but also to reflect and annotate the diversity of the observations (i.e., when distances between the transcription factor binding site and RNA polymerase are unusual). Second, we utilized fuzzy clustering methods [13,14] to encode promoter matching to multiple models for a given promoter feature, which avoided having to make premature categorical assignments, and producing an initial classification of the promoters into multiple subsets. Finally, we applied fuzzy
logic [15] to relate some basic features into more informative composite models that may explain the distinct expression behavior of genes belonging to similar networks (Fig. 2). A distinguishing characteristic of our approach is that promoters for orthologous genes are considered individually. This is in contrast to some phylogenetic footprinting methods [16] that often ignore regulatory differences among closely-related organisms due to their strict reliance on the conservation of regulatory motifs across bacterial species.

**Activated/repressed promoters**

Gene expression data normally allow clear separation of genes into those that are activated and those that are repressed by a regulatory protein. Because the expression signal is sometimes absent or too low to be informative, we considered the location of a transcription factor binding site relative to that of the RNA polymerase to separate promoters into activated and repressed subsets (Fig. 3A, B) [17].

We determined that the location of binding sites functioning in activation is different from that corresponding to sites functioning in repression (Fig. 3A, B), being centered ~40 and ~20 bp upstream of the transcription start site, respectively. This allowed us to distinguish among PhoP-regulated promoters that have apparently similar network motifs (Fig. 2). For example, we identified a PhoP binding site at a relative distance to the RNA polymerase consistent with repression in the promoter region of the hilA gene, which encodes a master regulator of *Salmonella* invasion and had been known to be under transcriptional repression by the PhoP/PhoQ system [18, 19]. Several promoters, including those of the *Salmonella* pipD and nmpC genes, were classified as candidates for being both activated and repressed, because the distance between the predicted transcription start site and the PhoP box is consistent with either activation or repression. Gene expression experiments conducted in *E. coli* indicate that nmpC is a PhoP-repressed gene [4-6]. Other promoters were predicted to have more than one PhoP box (e.g., those of the PhoP-activated mgtC and pagC genes), where by their location one could correspond to an activation site and the other to a repression site [20].

**Transcription factor binding site orientation**

Functional binding sites for a transcription factor may be present in either orientation relative to the RNA polymerase binding site [21]. This is due to the possibility of DNA looping and to the flexibility of the alpha subunit of the bacterial RNA polymerase in its interactions with transcriptional regulators [22, 23]. Yet, promoters harboring binding boxes in different orientation can be controlled by PhoP using the same network motif. That is the case of the yebG, and slyB (direct), compared to pagK and pagC (opposite) *Salmonella* promoters (Fig. 4A). Analysis of PhoP-regulated promoters revealed that the PhoP box could be found with the same probability in either orientation in the intergenic regions of the *E. coli* and *Salmonella* genomes (Fig. 5). For example, the *E. coli* ompT and yhiW promoters and the *Salmonella* mig-14, pipD, pagC and pagK promoters harbor putative PhoP binding sites in

---

**Figure 1**
The PhoP/PhoQ system employs a variety of network motifs to regulate gene transcription. (A) In the single-input module, PhoP as a single transcription factor regulates a set of genes (i.e. *mgtA, phoP, pmrD*). (B) In the multi-input module, two or more transcription factors (e.g., PhoP and RcsB) regulate a target gene (i.e. *ugd*). (C) In the bi-fan module, a set of genes (i.e. *pmrD* and *yrbL*) are each regulated by a combination of transcription factors (i.e. PhoP and PmrA). (D) In the chained motif, genes are regulated in an ordered cascade. (E) In the feedforward loop, a transcription factor (i.e. PhoP) regulates the expression of a second transcription factor (i.e. YhiW), and both jointly regulate one or more genes (i.e. *hdeA/D*).
PhoP-regulated promoters are described on the basis of five types of features. We conform a database including whether the position of the PhoP box suggests that a promoter is activated or repressed (activated/repressed); the orientation of the PhoP box (orientation); distinct PhoP box patterns (motif patterns); the distance of the PhoP box relative to the RNA polymerase site and the class of sigma 70 promoter (RNA polymerase sites); and the presence of potential binding sites for 24 transcription factors in the PhoP-regulated promoters (Other TFBs). The identification of a feature in a promoter is based on measuring the degree of match between a promoter instance and a model that represents that feature, which results in a vector of [0, 1] values where 1 (red) corresponds to maximum matching and 0 (green) corresponds to the absence of the feature. Individual genes are allowed to have more than one promoter because more than one candidate PhoP box can be identified in an intergenic region. In addition, promoters for the same gene in different genomes are considered separately in the E. coli and Salmonella genomes. Activated/repressed analysis discriminates among three groups (A1-A2) corresponding to activated, and repressed genes, respectively. The PhoP box could be present in the opposite (O1) or the same (O2) orientation as the regulated open reading frame. Pattern analysis of the PhoP box resulted in four preliminary groups (M1-M4). RNA polymerase sites analysis revealed six groups (P1-P6) corresponding to types and location of sigma 70 promoters: (1) close class II, (2) close class I, (3) medium class II, (4) medium class I, (5) remote class II and (6) remote class I. The presence of other transcription factor binding sites in PhoP-regulated promoters includes: (1) OxyR, (2) FruR, (3) DeoR, (4) MalT, (5) MelR, (6) CytR, (7) GlpR, (8) ArcA, (9) FNR, (10) RcsB, (11) Fur, (12) ArgR, (13) RhaS, (14) AraC, (15) CRP, (16) DnaA, (17) YhiW, (18) Lrp, (19) NarL, (20) FIS, (21) IHF, (22) OmpR, (23) PmrA and (24) SlyA.
Learning promoter features. Promoter features were learned as models from examples in databases (e.g., RegulonDB) and then used to describe the intergenic regions of the *E. coli* and *S. enterica* genomes. (A, B) Promoters were classified into activated (A), repressed (B) or both, based on the location and the distance of a regulatory protein binding site to the RNA polymerase site. Different distributions are observed for activated, repressed and activated/repressed genes. The property that characterizes activated genes was learned from distances between the transcription start sites (+1) and the binding sites of different transcription factors. These distances were grouped in histograms and codified as elastic (fuzzy) functions, which can be interpreted as the membership degrees (in a unit interval) by which subsets of the dataset can embrace this property. (B) The histogram and membership function corresponding to repressed promoters. μ is maximal at much closer distances. Thus, the promoter distances can be probabilistically interpreted as the posterior probability p(close/activated) that given an activated gene, the regulator binding site is at a close distance from the transcription start site, following Bayes' rule. (C) The distances between transcription start sites (+1) and the binding sites of regulators were grouped into a histogram and codified as elastic (fuzzy) unit-interval functions. This process is analogous to fitting data from a parametric or non-parametric distribution and then assigning probabilities of membership to such distributions. We used these models to characterize the relationships between binding sites for the PhoP protein and the RNA polymerase binding site in the genome. Relationships were classified according to their similarity (fuzzy membership) with the prototypes to obtain a similarity vector of expression values. (D) The histogram illustrates the distances for binding sites of different regulators sharing the same promoter regions. The resulting membership functions, which were learned from such distributions, allows evaluating the putative relationship between a transcription factor motif and a PhoP box based both on motif quality and physical location.
the opposite relative orientation to that described for the prototypical PhoP-activated mgtA promoter [4] (Fig. 2). Yet other promoters (i.e. those of the ybjX, slyB, pagK and pagC genes) in E. coli and the virK, ybjX, and mgtC genes in Salmonella) contain sequences resembling the PhoP box in both orientations. The demonstration that PhoP does bind to the mgtC, mig-14 and pagC promoters [4], which harbor the PhoP binding site in the opposite orientation as in the mgtA promoter, validates our predictions and argues against alternative network designs where these promoters would be regulated by PhoP only indirectly [24].

**Transcription factor binding site patterns**

Many genes are controlled by a single-input network motif where the affinity of a transcription factor for its promoter sequences is a major determinant of gene expression. Thus, co-regulated genes displaying distinct expression patterns are likely to differ in the binding site pattern. The PhoP protein recognizes a binding site motif consisting of a hexameric direct repeat separated by 5 bp, but distinguishes between different patterns with different specificities (i.e. phoP and pmrD). (C) PhoP regulates the phoP and mgtA Salmonella genes using the same network motif, however, mgtA harbors a riboswitch pattern in its 5'UTR region. (D) PhoP-regulated promoters differ in the distance between the PhoP box and the RNA polymerase site. The PhoP-activated ugtL and pagC promoters share the orientation of the PhoP-binding site as well as the class I sigma 70 promoter, but differ in the distance between the PhoP box and the RNA polymerase site. (E) Expression of PhoP-regulated promoters that use the bi-fan network motif. The Salmonella pmrD, and ugd promoters harbor experimentally verified PhoP- and PmrA-binding sites that can be described by the bi-fan network motif. The distance between the PhoP and PmrA boxes in the Salmonella pmrD and ugd promoters are also different (~38 bp and ~65 bp, respectively).
motors, such as that corresponding to the *E. coli* hdeA gene or the *Salmonella pmrD*, that had not been detected by the single position weight matrix model [26,28] despite being footprinted by the PhoP protein [4-6,10-12]. The use of four patterns instead of a single consensus increased the sensitivity for PhoP binding sites from 46% to 74%; yet, the specificity remained essentially the same (i.e., 98% in a consensus model versus 97%). Importantly, this approach is not exclusive to binding sites recognized by the PhoP protein, but for other transcription factors reported in the RegulonDB database [30], where we could increase the sensitivity in an average of 35%, while retain almost the same sensitivity than a single position weight matrix (O.H. *et al.*, manuscript in preparation).

**Riboswitch site patterns**

Riboswitches are structured domains that usually reside in the non-coding regions of mRNAs (UTRs), where they bind specific metabolites and control gene expression. The most common effects occur at the level of premature termination of transcription (cis-acting) or translation initiation. Upstream regions of PhoP regulated genes were screened for riboswitches by analyzing the presence of segments with conserved secondary structure across genomes and thermodynamic stability; because Rfam searches did not produce significant hits. Then, we evaluate if these candidate segments could be either small non-coding RNA or riboswitches, depending on their relative location to the beginning of the gene. Those candidates with conserved helixes, stable thermodynamically energy, and located close (<5 bp) to the translation start site of the closest gene, were further inspected as possible riboswitches. We found several genes with a long UTR region as possible candidates (see [http://gps-tools2.wustl.edu/data/riboswitch.xls](http://gps-tools2.wustl.edu/data/riboswitch.xls)). One of these genes is the *Salmonella mgtA* promoter, which has been experimentally validated (Fig. 4C) showing that the DNA corresponding to a 264 nucleotide riboswitch confers Mg2+ regulation when cloned in front of a reporter gene and behind a derivative of the lac promoter. Again, PhoP uses a similar network architecture to control promoters with differentially arranged regulatory regions (Fig. 4C).

**RNA polymerase binding site patterns and location**

The distance of a transcription factor binding site to the RNA polymerase binding site(s) and the class of sigma 70 promoter are critical determinants of gene expression [22]. These classes correspond to the different types of contacts that can be established between a transcription factor and RNA polymerase. We identified six patterns among PhoP-regulated promoters of *E. coli* and *Salmonella* (Fig. 2) that combine promoter class and distance between the PhoP box and the RNA polymerase site (Fig. 3C). These patterns may correspond to a similar network

---

**Figure 5**

**Statistical significance of PhoP-binding site orientation.** (A) PhoP-binding sites were discovered in both possible orientations relative to the open reading frame, even though all published PhoP-binding sites are reportedly only in one (i.e. direct) orientation. To test the hypothesis that the genome harbors the PhoP-binding site in either orientation, we collected the number of PhoP-binding sites both in intergenic and coding regions of the *Salmonella* and *E. coli* genomes at different specificity levels. % indicates the relationship with the maximum score obtained by the Consensus/Patser program with a single consensus motif. Using a 95% confidence interval, we could not reject the null hypothesis using one-way ANOVA. (B) Multiple tests illustrates that we did not find significant differences in pairwise comparisons among six sets generated by splitting the data by regions, motif scores and genomes (we use Matlab *multicomp* routine with corrections for multiple tests). The horizontal axis corresponds to rows in (A), and the vertical axis illustrates the group means of the columns in (B).

---

**Table**

| Genome  | Region | Orientation | >60% | >70% | >80% |
|---------|--------|-------------|------|------|------|
| *Salmonella* | IG     | Direct      | 261  | 68   | 19   |
|          | Reverse |            | 257  | 76   | 20   |
| Coding   | Direct |             | 350  | 82   | 21   |
|          | Reverse|             | 325  | 93   | 24   |
| *E. coli* | IG     | Direct      | 250  | 70   | 17   |
|          | Reverse|             | 226  | 57   | 13   |
| Coding   | Direct |             | 350  | 92   | 21   |
|          | Reverse|             | 301  | 87   | 15   |
motif, as it is the case of the *ugtL* and *pagC* promoters, which share the orientation of the PhoP box but differ in the distance of the PhoP box to the RNA polymerase binding site [22] (Fig. 4D).

Some PhoP-regulated promoters (e.g. the *hemL* and *phoP* promoters of *E. coli*) contain several putative RNA polymerase binding sites located at different positions and belonging to different classes, suggesting that such promoters may be regulated by additional signals and/or transcription factors [6]. The RNA polymerase site feature was evaluated using 721 RNA polymerase sites from RegulonDB as positive examples and 7210 random sequences as negative examples. We obtained an 82% sensitivity and 95% specificity for detecting RNA polymerase sites. These values provide a false discovery rate <0.001 and a correlation coefficient of 82%. In addition, we selected 34 examples of RNA polymerase sites reported to be of class II, which all differ from the typical class I promoter by exhibiting a degenerate -35 sequence motif [6,22,32], and obtained 74% sensitivity and 95% specificity.

**Binding sites for other transcription factors**

Certain promoters harbor binding sites for more than one transcription factor. This could be because transcription requires the concerted action of such proteins, or because the promoter is independently activated by individual transcription factors, each responding to a distinct signal.

We analyzed the intergenic regions of the *E. coli* and *Salmonella* genomes for the presence of binding sites for 54 transcription factors [30]. We then investigated the co-occurrence of 24 sites with the binding site of the PhoP protein in an effort to uncover different types of network motifs involving PhoP-regulated promoters. For example, the *Salmonella* *pmrD*, *ugd* and *yrbL* promoters and the *E. coli* *yrbL* promoter harbor PhoP- and PmrA-binding sites, consistent with the experimentally-verified regulation by both the PhoP and PmrA proteins that can be described by the bi-fan network motif [4,33] (Fig. 4E). In addition, the relative position of transcription factor binding sites (Fig. 3D) can play a critical role because the PmrA-box in the *Salmonella* *pmrD* and *yrbL* promoters is located closer to the PhoP-box (~38 bp and ~24 bp, respectively) than in the *udg* promoter (~65 bp). By analyzing both the binding site quality and the location of transcription factor binding sites, we increase the chances of identifying co-regulated promoters.

By considering the presence of binding sites for multiple transcription factors, it is possible to generate hypotheses about potential network motifs. For example, the promoters of the PhoP-activated *gadA*, *dps*, *hdeA*, *yhiE* and *yhiW* genes of *E. coli* also have binding sites for the regulatory proteins YhiX and YhiE [4], raising the possibility that some of these genes might be regulated by feedforward loops where both the PhoP protein and either the YhiW or the YhiE proteins would bind to the same promoter to activate transcription. This notion was experimentally verified [4], validating our prediction.

### Evaluating the effect of distinct cis-regulatory features within a network motif

Gene expression is often measured by binary assays that evaluate differentials between wild-type and mutant strains (e.g., typical microarrays). These experiments always help to differentiate activated from repressed genes, and sometimes very low from very highly expressed genes. However, these approaches often conceal quantitative differences between true expressed genes. We hypothesize that distinct promoter features may affect gene expression even in similarly arranged network motifs. To test this notion, we compared the gene expression patterns of wild-type *Salmonella* harboring plasmids with a transcriptional fusion between a promoterless *gfp* gene to different PhoP-activated promoters (Fig. 6).

We found that promoters that differ in the orientation of the PhoP binding site and are arranged in a similar network motif such as *slyB* and *pagC* produce a complete different patterns of expression (Fig. 4A, 6). Moreover, single-output network motif including the *phoP* and the *pmrD* genes (Fig. 4B), which exhibit different PhoP box patterns, reveal a substantial different levels of promoter activity as measured by GFP kinetics (Fig. 6). Within the same network motif, we also evaluated the *mgtA* promoter and found that without specific primers for the 5'-UTR region the gene is unable to transcribe (Fig. 4C, 6). This suggests that the riboswitch located in the promoter region of *mgtA* is a critical feature that distinguishes promoters within the similar network (Fig. 4C). The *ugtL* and *pagC* promoters share the orientation and the PhoP box but differ in the distance of the PhoP box to the RNA polymerase binding site (Fig. 4D). This may account for the different kinetic behavior of these promoters when tested in a wild-type strain harboring plasmids with promoter fusions to the promoterless *gfp* gene (Fig. 6).

We also realized that the expression patterns differ in other types of network motifs such as the bi-fan. The *Salmonella* *pmrD* and *ugd* promoters harbour experimentally validated PhoP- and PmrA-boxes [10,34] (Fig. 4E), and both promoters confer distinct levels of expression as well as kinetic patterns (Fig. 6). Although it is hard to discern the specific and individual influence of each type of cis-feature, the preliminary results obtained by *gfp* experiments suggest that those regulatory elements described above can effectively produce differential gene expression even within similar network motifs.
Global transcriptional regulators control multiple promoters by a variety of network motifs [27]. This is clearly the case for the regulatory protein PhoP (Fig. 1). In this work, we studied this regulatory protein and demonstrated that understanding gene expression does not only require identifying a set of connexions or network motif, but also the cis-acting elements participating in each of these connexions.

**Materials and methods**

Our method consists of three phases: first, encoding the available information into preliminary model-based features, which includes identifying cis-features from DNA sequences and information from available databases; performing initial modeling of each individual feature, allowing the process of multiple occurrences of a feature and using relaxed thresholds and permitting missing values. A model-based feature is generated by the identification of a feature in a subset of observations (F) in the dataset, based on measuring the degree of match (Q) between an observation and a model, or a family of models (M = {Mα}), at some degree (α) defined in a unit-interval scale (i.e., fuzzy values, Q(F, Mα)) [35,36]. Second, grouping the results into subsets, thus, decomposing the preliminary models into a family of models or building blocks by using fuzzy clustering (see Additional file 1). Third, composing the building blocks by either combining the same or different types of features by using fuzzy logic expressions (see Additional file 1). And fourth, describing new promoters using the resulting models.

**Network motifs**

In theory, the term "network motifs" is related to a statistical significant subgraph; however, in practice, they are treated as an over represented subgraph [37,38]. For example, a motif termed "single input motif " of three/four nodes in the E. coli (e.g., mfinder1.2 p-value < 34.7+-8.5) or Saccharomyces cerevisiae network [39] is not recognized as significant, while the only motif that exceeds the standard threshold is the "feed forward motif".

**Activated/repressed**

We modeled PhoP-regulated promoters as activated or repressed based on examples reported in the RegulonDB database [30]. (1) We separately grouped activated and repressed promoters, and plotted histograms for each group corresponding to the distances between transcription factor binding sites and the transcription initiation (+1) site. (2) We distinguished two non-disjoint distributions in each group and built models for these distances by fitting histograms with fuzzy membership functions [15] (Fig. 3A, B) (see Additional file 1), which do not force promoters to be exclusively Activated or Repressed. (3) Finally, we connected (2) and sigma 70 promoters previously detected to select the most representative candidate

**Conclusion**

We demonstrated that a transcription factor could mediate differential expression of genes described by the same network motif. This is because of the functional significance of variability in sequence, location and topology that exists among promoters that are co-regulated by a given transcription factor. We developed methods that encode and combine these promoter features, which allows matching of cis-observations to multiple models for a given promoter feature, into flexible databases constituting annotations of genome regulatory regions. These annotations cannot be uncovered by simpler sequence analysis approaches (Fig. 7). Indeed, the developed methods can be used to search and predict regulatory features even in incompletely characterized organism. Notably, these features do not constitute a computational artifact, but reflect different kinetic behaviours of co-regulated genes.

Figure 6

Measurements of promoter activity and growth kinetics for GFP reporter strains with high-temporal resolution. Transcriptional activity of wild-type Salmonella harboring plasmids with a transcriptional fusion between a promoterless gfp gene and the Salmonella promoters including phoP (blue), pmrd(green), slyB (red), pagC (cyan), ugd(magenta), ugtL (yellow) and mgtA (orange). Each experiment was conducted independently at least twice, and shown after preprocessing. The activity of each promoter is proportional to the number of GFP molecules produced per unit time per cell \[dG(t)/dt]/OD(t)], where G(t) is GFP fluorescence from wild-type Salmonella strain 14028s culture and conditions described in Methods, and OD(t) is the optical density. The activity signal was smoothed by a polynomial fit (sixth order).
We built an initial model for the PhoP binding site by learning a position weight matrix [28] (E-value < 10E-12) based on the upstream sequences of genes corresponding to the training set of the *E. coli* and *Salmonella* genomes (Table S1, Additional file 1). (2) We searched the intergenic regions of the genes in both orientations, using low thresholds corresponding to two standard deviations below the mean score obtained with the initial model [40]. Multiple PhoP binding site candidates were allowed in a given promoter operator region. (3) After transforming nucleotides into dummy variables [41], we grouped sequences matching the PhoP position weight matrix using the fuzzy C-means clustering method with the Xie-Beni validity index (see Additional file 1) to estimate the number of clusters [13,42]. (4) We built models for these clusters using position weight matrices (E-value < 10E-22) and searched the *E. coli* and *Salmonella* genomes to characterize each gene according to its similarity to each model as a fuzzy partition (Fig. 2).

**Binding site patterns and orientation**

(1) We built an initial model for the PhoP binding site by learning a position weight matrix [28] (E-value < 10E-12) based on the upstream sequences of genes corresponding to the training set of the *E. coli* and *Salmonella* genomes (Table S1, Additional file 1). (2) We searched the intergenic regions of the genes in both orientations, using low ordinary means clustering method with the Xie-Beni validity index (see Additional file 1) to estimate the number of clusters [13,42]. (4) We built models for these clusters using position weight matrices (E-value < 10E-22) and searched the *E. coli* and *Salmonella* genomes to characterize each gene according to its similarity to each model as a fuzzy partition (Fig. 2).

**Riboswitch site patterns**

(1) We employed upstream regions of PhoP regulated genes to create conserved sequence alignments by comparisons against representative proteobacterial genomes. We used WU BLAST 2.0 http://blast.wustl.edu[43] with a word hit of eight, and using default parameters otherwise. (2) We selected alignments with an E-value ≤ 0.00001 and
a length ≥ 50 nt; and divided alignments longer than 300 bp into windows of 300 bp with 50 bp of overlap. (3) These windows fed the programs eQRNA and RNAz following the protocol described in [44] using a window size of 200 nucleotides and a window slide increment of 50 nucleotides. QRNA analysis was performed with eQRNA version 2.0.3c. (ftp://selab.janelia.org/pub/software/qrna/). (3.1) We classified the alignment as RNA, coding, or other, according to the posterior probability of each model. RNAz was used with its version 0.1.1 http://www.tbi.univie.ac.at/~wash/RNAz. We only considered overlapping eQRNA and RNAz predictions for the upstream regions of PhoP regulated genes as candidates for small non-coding RNA or riboswitches. (4) We encoded the conservation identity of the segments and their distance to the translation start site of the closest gene as fuzzy sets; and aggregated them using fuzzy expressions (see Additional file 1). (5) All fuzzy expressions of a single gene were combined using the Maximum T-conorm (see Additional file 1).

**RNA polymerase sites**

(1) We gathered sigma 70 class I and class II promoters [32,45] from the RegulonDB database and [46]. Then, we built models of the RNA polymerase site using a neuro-fuzzy method (see HPAM in http://gps-tools2.wustl.edu[47]), and used the resulting models to perform genome-wide descriptions of the intergenic regions of the *E. coli* and *Salmonella* genomes with a false discovery rate <0.001 (see Promoter search in http://gps-tools2.wustl.edu). (2) We used an intelligent parser to differentiate class I and class II promoters that evaluate the quality of the -35 motif [22,32], based on fuzzy logic (see Additional file 1) and genetic algorithms techniques (see MOSS in gps-tools2.wustl.edu [48]). (3) To characterize the distance relationship between transcription factors binding sites and RNA polymerase binding sites, we built models of such distances from the examples reported in the RegulonDB database. (3.1) We modeled activated and repressed promoters (see below Activated or repressed feature). (3.2) We re-built histograms for each group of distances (i.e. activated and repressed), distinguishing three overlapping distributions for each of them. (3.3) We built models for distances by fitting their distributions into models based on fuzzy membership functions [15] (see Additional file 1), which were termed close, medium and remote distances for each set of activated and repressed genes (Fig. 3C). Finally, to characterize the distance relationship between the PhoP box and putative RNA polymerase binding site, we connected (2) and (3) by using fuzzy logic-based operations (see Additional file 1).

This process allowed us to retrieve the most representative RNA polymerase binding site candidates for each promoter region relative to the PhoP binding site (e.g., best class II RNA polymerase site, which is located close to the PhoP box in an activated promoter), which were arrayed and constituted the value of the RNA polymerase site feature in Fig. 2. The probabilistic interpretation of the former process is usually the posterior probability (e.g., p(class II|close) that, given a close promoter, it comes from class “class II” by following Bayes’ rule [13,41,42]). This process is analogous to classification methods termed Naïve Bayes [49] if the T-norm and the T-conorm (see Additional file 1) are restricted to the Product and the Maximum.

**Binding sites for other transcription factors**

We developed models for different transcription factor binding sites from the RegulonDB database as follows: (1) We built position weight matrices for each transcription factor using the Consensus/Patser program, choosing the best final matrix for motif lengths between 14–30 bps if the corresponding length had not been previously specified (see “Consensus matrices” in http://gps-tools2.wustl.edu). We accounted for the motif symmetry (e.g., asymmetric, direct, inverted [45]) if available (see “Search known transcription factor motifs” in http://gps-tools2.wustl.edu). (2) We searched the intergenic regions of the *E. coli* and *Salmonella* genomes with these models, using the correlation coefficient measure (see Additional file 1) and additional 772 promoters from the RegulonDB database [30] to establish a threshold (average E-value < 10E-10) for each matrix [50] (see “Thresholded consensus” in http://gps-tools2.wustl.edu). (3) We accounted for the distances between distinct transcription factors binding sites occurring in the same promoter region (e.g., the distance between the CRP and FIS sites in the proP promoter [51]) in promoters reported in RegulonDB database and built a histogram with the obtained results (Fig. 3D). (4) We fitted the histogram using a fuzzy membership function (see Additional file 1) and used this model as a fuzzy cluster to characterize the distances between a putative PhoP box and another putative transcription factor binding site detected in the same region. (5) Finally, we connected (2) and (4) by using fuzzy logic-based operations (see Additional file 1), which can also have a probabilistic interpretation (e.g., p(CRP, FIS/appropriate distance) upstream of the proP open reading frame of *E. coli*), to characterize PhoP regulated candidates promoters.

**Dataset**

We initially used the intergenic regions of *E. coli* and *Salmonella* operons from -800 to +50 because > 5% are larger than 800 bp in bacterial genomes (as described in the RegulonDB database or generously provided by H. Salgado) [49]; however, predictions have been performed in whole coding and non coding regions (see http://gps-tools2.wustl.edu). The promoter and transcription factor
information was taken from RegulonDB database. We compiled from the literature and our own lab information (Table S1, Additional file 1) genes whose expression (using microarrays) differed statistically between wild-type and phoP E. coli strains experiencing inducing conditions for the PhoP/PhoQ regulatory system [4], as well as a list of genes known/assumed to be PhoP regulated [52]. However, this information did not explicitly indicate whether these genes were regulated directly or indirectly by the PhoP protein. The learned features were used to make genome-wide predictions in the E. coli and Salmonella genomes.

Programming resources
The scripts and programs used in this work, some of which are accessible from http://gps-tools2.wustl.edu web site, were based on Perl, Matlab r2006a and C++ interpreters/languages, and the visualization routines were performed on Spotfire DecisionSite software 8.2. Data and predictions for E. coli and Salmonella genomes are available at supplemental table S1 in Additional file 1 and at http://gps-tools2.wustl.edu.

Bacterial strains, plasmids and growth conditions
Bacterial strains and plasmids used in this study are listed in Table S2, Additional file 1. Salmonella enterica serovar Typhimurium strains used in this study are derived from strain 14028s. Bacteria were grown at 37°C in Luria-Bertani broth (LB) [53] or N-minimal medium pH 7.7 [54] supplemented with 0.1% Casamino Acids, 38 mM glycerol, MgCl₂. Kanamycin was used at 25 μg/ml.

Constructions of GFP reporter plasmids
Promoter regions (i.e. the intergenic region between two ORFs) were amplified using PCR. A list of the promoter-specific primers used in the PCR reactions is shown in Table S3, Additional file 1. The PCR fragment was digested with BamHI and XhoI, purified, then introduced to the cloning site of pMS201 (GFP reporter vector plasmid, a gift from Alon, U. [55]). Sequences of promoter region used to construct the promoters in GFP reporter plasmids. Table S2 details the bacterial strains and plasmids used in this study, and Table S3 the primers used to construct the promoters in GFP reporter plasmids.

Competing interests
The authors declare that they have no competing interests.

Authors’ contributions
OH and IZ designed and implemented the methods and wrote the manuscript; CV designed and implemented the riboswitch identification methods; RRZ coded the perl scripts and the web page; DS performed the experimental validation using GFP technology; HH provided advice on the project and revised the manuscript; EAG supported the project and drafted the manuscript.

Additional material

Additional File 1
Supplemental tables. Table S1 provide the features describing PhoP regulated promoters and raw data used to build them. Table S2 details the bacterial strains and plasmids used in this study, and Table S3 the primers used to construct the promoters in GFP reporter plasmids.

Acknowledgements
We thank U. Alon (Weizmann Institute of Science, Israel) for plasmid pMS201, and Elena Rivas (Janelia Farm Research Campus, Howard Hughes Medical Institute) for providing the computational tools to identify riboswitches. This research was supported in part by the Spanish Ministry of Science and Technology under project TIN2006-12879 and by Consejería de Innovación, Investigación y Ciencia de la de la Junta de Andalucía under project TIC02788. E.A.G. is an Investigator of the Howard Hughes Medical Institute.
