We study the extraction of the ground-state parameters from vacuum-to-vacuum correlators. We work in quantum-mechanical potential model which provides the only possibility to probe the reliability and the actual accuracy of this method: one obtains the bound-state parameters from the correlators by the standard procedures adopted in the method of sum rules and compares these results with the exact values calculated from the Schrödinger equation. We focus on the crucial ingredient of the method of sum rules — the effective continuum threshold — and propose a new algorithm to fix this quantity. In a quantum-mechanical model, our procedure leads to a remarkable improvement of the accuracy of the extracted ground-state parameters compared to the standard procedures adopted in the method and used in all previous applications of dispersive sum rules in QCD. The application of the proposed procedure in QCD promises a considerable increase of the accuracy of the extracted hadron parameters.

Keywords: Nonperturbative QCD, hadron properties, QCD sum rules

1. INTRODUCTION

The extraction of the ground-state parameters from the operator product expansion (OPE) series for a relevant correlator is a cumbersome procedure: even if several terms of the OPE for the correlator are known precisely, the numerical procedures of the method of dispersive sum rules cannot determine the true exact value of the bound-state parameter. Instead, the method should provide the band of values such the true hadron parameter has a flat probability distribution within this band. This band is a systematic, or intrinsic, sum-rule uncertainty.

The method of sum rules in QCD contains a set of prescriptions (see e.g. [3, 4]) which are believed to provide such a systematic error. In QCD this, however, always remains a conjecture — it is impossible to prove that the range provided by the standard sum-rule procedures indeed contains the actual value of the bound-state parameter.

The only possibility to acquire unbiased judgement of the reliability of the error estimates in sum rules is to apply the method to a problem where the parameters of the theory may be fixed and the corresponding parameters of the ground state may be calculated independently and exactly. Presently, only quantum-mechanical potential models provide such a possibility.

A simple harmonic-oscillator (HO) potential model [4, 5, 6, 7] possesses the essential features of QCD — confinement and asymptotic freedom [8] — and has the following advantages: (i) the bound-state parameters (masses, wave functions, form factors) are known precisely; (ii) direct analogues of the QCD correlators may be calculated exactly. (For a discussion of many aspects of sum rules in quantum mechanics we refer to [9, 10, 11, 12, 13, 14]).

Making use of this model, we have already studied the extraction of ground-state parameters from different types of correlators: namely, the ground-state decay constant from two-point vacuum-to-vacuum correlator [4], the form factor from three-point vacuum-to-vacuum correlator [5], and form factor from vacuum-to-hadron correlator [6]. We have demonstrated that the standard adopted procedures for obtaining the systematic errors do not work properly: for all types of correlators the true known value of the bound-state parameter was shown to lie outside the band obtained according to the standard criteria. These results give a solid ground to claim that also in QCD the actual accuracy of the method turns out to be much worse than the accuracy expected on the basis of the standard criteria applied.

Thus, our results reported in [4, 5, 6, 7] mainly contained cautious messages concerning the application of sum rules to hadron properties. However, understanding the problem is the necessary first step in solving the problem.

We have realized that the main origin of this failure of the method lies in an over-simplified model for hadron continuum which is described as a perturbative contribution above a constant Borel-parameter independent effective continuum threshold. We have introduced the notion of the exact effective continuum threshold, which corresponds to the true bound-state parameters: in a HO model the true hadron parameters — decay constant and form factor — are known and the exact effective continuum thresholds for different correlators may be calculated. We have demonstrated that the exact effective continuum threshold (i) is not a universal quantity and depends on the correlator considered (i.e. it is in general different for two-point and three-point vacuum-to-vacuum correlators), and (ii) depends on the
The solution G\(\equiv (H - E)^{-1}\) and the free Green function \(G_0(E) \equiv (H_0 - E)^{-1}\) are related by
\[ G^{-1}(E) - G_0^{-1}(E) = V. \] (2.2)

The solution \(G(E)\) of this relation may be easily obtained as an expansion in powers of the interaction \(V\):
\[ G(E) = G_0(E) - G_0(E)VG_0(E) + \cdots. \] (2.3)

In the HO model, all characteristics of the bound states are easily calculable. For instance, for the ground state (g), \(n = 0\), one finds
\[ E_g = \frac{3}{2}\omega, \quad R_g = |\psi_g(\vec{r} = 0)|^2 = \left(\frac{m\omega}{\pi}\right)^{3/2}, \quad F_g(q) = \exp(-q^2/4m\omega), \] (2.4)

where the elastic form factor of the ground state is defined in terms of the ground-state wave function \(\psi_g\) according to
\[ F_g(q) = \langle \Psi_g | \hat{J}(\vec{q}) | \Psi_g \rangle = \int d^3k \psi_g^*(\vec{k})\psi_g(\vec{k} - \vec{q}) = \int d^3r |\psi_g(\vec{r})|^2 e^{i\vec{q}\vec{r}}, \quad q = |\vec{q}|, \] (2.5)

and the current operator \(\hat{J}(\vec{q})\) is given by the kernel
\[ \langle \vec{r}' | \hat{J}(\vec{q}) | \vec{r} \rangle = \exp(i\vec{q}\vec{r})\delta^{(3)}(\vec{r}' - \vec{r}). \] (2.6)

3. POLARIZATION OPERATOR

The quantum-mechanical analogue of the polarization operator has the form
\[ \Pi(T) = \langle \tilde{r}_f = 0 | \exp(-HT) | \tilde{r}_i = 0 \rangle. \] (3.1)
This quantity is used in the sum-rule approach for the extraction of the wave function at the origin (i.e., of the decay constant) of the ground state [1]. A detailed analysis of the corresponding procedure for the HO model can be found in [4]. For the HO potential, the analytic expression for \( \Pi(T) \) is well-known [8]:

\[
\Pi(T) = \left( \frac{\omega m}{\pi} \right)^{3/2} \frac{1}{[2\sinh(\omega T)]^{3/2}}.
\]

(3.2)

Apart from the overall factor, \( \Pi(T) \) is a function of one parameter \( T\omega \).

The average energy of the polarization function is defined as

\[
E_{\Pi}(T) \equiv -\partial_T \log \Pi(T) = \frac{3}{2} \omega \coth(\omega T), \quad \partial_T \equiv \frac{\partial}{\partial T}.
\]

(3.3)

At \( T = 0 \) both \( \Pi(T) \) and \( E_{\Pi}(T) \) diverge. For large values of \( T \) the contributions of the excited states to the correlator vanish and therefore \( E_{\Pi}(T) \to E_{g} \) for \( T \to \infty \). The deviation of the energy from \( E_{g} \) at finite values of \( T \) measures the “contamination” of the correlator by the excited states.

The ground-state contribution to the correlator has a simple form:

\[
\Pi_{g}(T) = \left( \frac{\omega m}{\pi} \right)^{3/2} \exp \left( -\frac{3}{2} \omega T \right).
\]

(3.4)

The OPE series is the expansion of \( \Pi(T) \) at small Euclidean time \( T \):

\[
\Pi_{\text{OPE}}(T) = \left( \frac{m}{2\pi T} \right)^{3/2} \left( 1 - \frac{1}{4} \omega^2 T^2 + \frac{19}{480} \omega^4 T^4 + \cdots \right).
\]

(3.5)

For \( \Pi(T) \) this expansion is equivalent to the expansion in powers of the interaction \( \omega \).

The first term in (3.5) does not depend on the interaction and describes the free propagation of the constituents. \( \Pi_{0} \) may be written as the spectral integral [4]

\[
\Pi_{0}(T) = \int dz e^{-zT} \rho_{0}(z), \quad \rho(z) = \frac{2}{\sqrt{\pi}} e^{-z},
\]

(3.6)

with \( \rho_{0}(z) \) the known spectral density of the one-loop two-point Feynman diagram of the nonrelativistic field theory [4]. The rest of the series represents power corrections, which may be obtained just as the difference between the exact correlator and the free-propagation term:

\[
\Pi_{\text{power}}(T) = \Pi(T) - \Pi_{0}(T).
\]

(3.7)

4. VERTEX FUNCTION

The basic quantity for the extraction of the form factor in the method of dispersive sum rules is the correlator of three currents [2]. The analogue of this quantity in quantum mechanics reads [5, 13]

\[
\Gamma(E_{2}, E_{1}, q) = \langle \vec{r}_{f} = 0 | (H - E_{2})^{-1} J(\vec{q}) (H - E_{1})^{-1} | \vec{r}_{i} = 0 \rangle, \quad q \equiv |\vec{q}|,
\]

(4.1)

[with the operator \( J(\vec{q}) \) defined in (2.6) and its double Borel (Laplace) transform under \( E_{1} \to \tau_{1} \) and \( E_{2} \to \tau_{2} \)]

\[
\Gamma(\tau_{2}, \tau_{1}, q) = \langle \vec{r}_{f} = 0 | G(\tau_{2}) J(\vec{q}) G(\tau_{1}) | \vec{r}_{i} = 0 \rangle, \quad G(\tau) \equiv \exp(-H\tau).
\]

(4.2)

For large \( \tau_{1} \) and \( \tau_{2} \) the correlator is dominated by the ground state:

\[
\Gamma(\tau_{2}, \tau_{1}, q) \rightarrow |\Psi_{g}(\vec{r} = 0)|^{2} e^{-E_{g}(\tau_{1} + \tau_{2})} F_{g}(q^{2}) + \cdots.
\]

(4.3)

Let us notice the Ward identity which relates the vertex function at zero momentum to the polarization operator:

\[
\Gamma(\tau_{2}, \tau_{1}, q = 0) = \Pi(\tau_{1} + \tau_{2}).
\]

(4.4)

This expression follows directly from the current conservation relation

\[
J(\vec{q} = 0) = 1.
\]

(4.5)
Fig. 1: Relative ground-state contribution to the energy $E_g(T, q)/E_{Γ}(T, q)$ (a) and to the correlator $Γ_g(T, q)/Γ(T, q)$ (b) vs. $T$ for several values of $q$. Solid (red) line: $q = 0$; dashed (green) line: $q = 1.5\sqrt{mω}$; dash-dotted (blue) line: $q = 3\sqrt{mω}$.

A. Exact $Γ(T, q)$ in the HO model

We obtain the exact $Γ(τ_2, τ_1, q)$ by using the known expression for the Green function in configuration space

$$⟨\vec{r}'|G(τ)|\vec{r}⟩ = Π(τ) \exp\left(-\frac{mωr^2}{2}\tanh^{-1}(ωτ)\right).$$

(4.6)

All necessary integrals are Gaussian and we easily derive an explicit expression for $Γ(τ_2, τ_1, q)$. For our further investigation, we consider the vertex function for equal times $τ_1 = τ_2 = \frac{1}{2}T$, which reads

$$Γ(T, q) = Π(T) \exp\left(-\frac{q^2}{4mω}\tanh\left(\frac{ωT}{2}\right)\right).$$

(4.7)

The correlator $Γ$ is a function of two dimensionless variables $ωT$ and $q^2/mω$. Setting, without loss of generality, $m = ω$ we still have 2 dimensionless variables $ωT$ and $q/ω$. This will be done later for the numerical analysis.

The corresponding average energy is defined as follows

$$E_{Γ}(T, q) ≡ -\partial_T \log Γ(T, q) = \frac{3}{2}ω \coth(ωT) + \frac{q^2}{4m} \frac{1}{(1 + \cosh(ωT))}.$$  

(4.8)

The contribution of the ground state to the correlator, $Γ_g$, in the HO model has the form

$$Γ_g(T, q) = \left(\frac{mω}{π}\right)^{3/2} \exp\left(-\frac{3}{2}ωT\right) \exp\left(-\frac{q^2}{4mω}\right).$$

(4.9)

The average energy $E_{Γ}$ and the ground-state contribution $Γ_g$ vs. $T$ for different values of $q$ are shown in Fig. II

First, notice that the on-set of the ground-state dominance in the correlator is shifted to later times with growing $q$. Second, if the ground-state energy $E_g$ is known (hereafter we will be discussing precisely this situation), the deviation of the average correlator energy from the ground-state energy may be used as an indicator of the ground-state contribution to the correlator. This indicator is, however, not very accurate: the relative contribution of the ground state to the correlator turns out to be systematically greater than the deviation of the average correlator energy from the ground-state energy.

Figure II makes obvious the way in which the ground-state form factor may be extracted from the correlator $Γ(T, q)$ known numerically (e.g., from the lattice): The correlator is dominated by the ground state at large values of $T$; so one may calculate the $T$- and $q$-dependent energy $E_{Γ}(T, q)$ which exhibits a plateau at large $T$: $E(T, q) → E_g$ for any $q$. Making sure that one has already reached the plateau and that the correlator is saturated by the ground state, one obtains the form factor from the relation

$$F_g(q) = \lim_{T→∞} \frac{1}{R_g} e^{E_g T} Γ(T, q).$$

(4.10)
B. OPE for $\Gamma(T,q)$

Let us now construct for $\Gamma(T,q)$ the analogue of the OPE as used in the method of three-point sum rules in QCD. The corresponding procedure consists of two steps: First, we expand $\Gamma$ in powers of $\omega^2$ and obtain

$$\Gamma(T,q) = \sum_{n=0}^{\infty} \Gamma_{2n}(q,T)\omega^{2n}. \quad (4.11)$$

Explicitly, for the lowest terms one has

$$\Gamma_0(T,q) = \left( \frac{m}{2\pi T} \right)^{3/2} \exp \left( -\frac{q^2 T^2}{8m} \right),$$
$$\Gamma_2(T,q) = \left( \frac{m}{2\pi T} \right)^{3/2} \exp \left( -\frac{q^2 T^2}{8m} \right) \left( -\frac{1}{4} + \frac{q^2 T}{96m} \right) \omega^2 T^2. \quad (4.12)$$

The first term, $\Gamma_0$, corresponds to free propagation and does not depend on the confining potential. It may be written as the double spectral representation [12]

$$\Gamma_0(T,q) = \int dz_1dz_2 e^{-\frac{i}{4}z_1T} e^{-\frac{i}{4}z_2T} \Delta_0(z_1,z_2,q), \quad \Delta_0(z_1,z_2,q) = \frac{m^2}{4\pi^2q^2} \theta \left( \left( z_1 + z_2 - \frac{q^2}{2m} \right)^2 - 4z_1z_2 < 0 \right). \quad (4.13)$$

The Ward identity in nonrelativistic field theory relates to each other the three-point function at zero momentum transfer and the two-point function and leads to

$$\lim_{q \to 0} \Delta_0(z,z',q) = \delta(z-z')\rho_0(z). \quad (4.14)$$

For the calculation of higher-order terms $\Gamma_{2n}$, $n \geq 1$, the explicit form of the confining potential is necessary. In the HO model it makes no problem to calculate all higher-order terms explicitly. Recall, however, that in QCD the situation is different: the confining potential is not known and therefore nonperturbative long-distance effects are parameterized as power corrections in terms of local condensates. Thus, for each quantity $\Gamma_{2n}$, $n \geq 1$, one has a power-series expansion in $T$. To keep the same track, we expand $\Gamma_{2n}$, $n \geq 1$, in powers of $T$. As the result of this procedure, the quantum-mechanical analogue of the OPE for $\Gamma$ takes the form

$$\Gamma_{\text{OPE}}(T,q) = \Gamma_0(T,q) + \Gamma_{\text{power}}(T,q),$$
$$\Gamma_{\text{power}}(T,q) = \left( \frac{m}{2\pi T} \right)^{3/2} \left[ -\frac{1}{4} \omega^2 T^2 + \frac{q^2 \omega^2}{24m} T^3 + \left( \frac{19}{480} \omega^4 - \frac{5q^4 \omega^2}{1536m^2} \right) T^4 + \cdots \right]. \quad (4.15)$$

We display here only terms up to $O(T^4)$ in $\Gamma_{\text{power}}$. For the practical extraction of the ground-state form factor we can retain any number of higher-order terms, which may be easily generated from the exact expression [17].

It should be emphasized that the coefficients of each power of $T^n$ in the square brackets of (4.15) are polynomials in $q^2$ of order $(n-2)$. Therefore, if the momentum $q$ increases, one needs to include more and more power corrections in order to achieve a certain accuracy of the truncated OPE series for $\Gamma$. In QCD, this implies the necessity to know and include condensates of higher and higher dimensions. Since only a few lowest-order condensates are known, in practice the applicability of three-point sum rules in QCD is restricted to the region of not too large $q^2$ and $T$.

Figure 2 demonstrates the behaviour of the exact correlator and the truncated OPE for different numbers of power corrections retained in the expansion and for several values of the momentum transfer $q$. Clearly, retaining a fixed number of power corrections and requiring the accuracy of the truncated OPE to be better than say 1% for $\omega T \leq 1.2$ restricts the region of the momentum transfer to “not very large” values. As is clear from Figs. 1 and 2 in the region of $\omega T$ where the truncated OPE provides a good description of the exact correlator, the contribution of the excited states is still rather large, i.e., one is still rather far from the plateau. Therefore, a direct determination of the form factor from a truncated OPE is not possible. The procedures of the method of sum rules are aimed at modifying the contribution of higher states to the correlator and at obtaining in this way the ground-state form factor.

5. SUM RULES AND EXACT EFFECTIVE CONTINUUM THRESHOLD

The sum rules for the two-point correlator $\Pi$ and the three-point correlator $\Gamma$ are merely an expression of equality of these correlators calculated in the “quark” and in the hadron basis:

$$R_g e^{-E_g T} + \Pi_{\text{excited}}(T) = \Pi_0(T) + \Pi_{\text{power}}(T), \quad (5.1)$$
$$F_g(q) R_g e^{-E_g T} + \Gamma_{\text{excited}}(T,q) = \Gamma_0(T,q) + \Gamma_{\text{power}}(T,q). \quad (5.2)$$
the effective continuum threshold does depend sizeably on both
number of such states. In the language of hadronic states, this correlator contains contributions of an infinite
treshold.

Making use of the standard quark-hadron duality assumption — that the contribution of the ground state is dual to
the low-energy region — we obtain the following duality relations:¹

\[ R_8 e^{-E_g T} = \int_0^{z_{\text{eff}}(T)} dz e^{-zT} \rho_0(z) + \Pi_{\text{power}}(T) \equiv \Pi_{\text{dual}}(T, z_{\text{eff}}^I(T)), \]  
\[ F_8(q) R_8 e^{-E_g T} = \int_0^{z_{\text{eff}}(T,q)} dz_1 \int_0^{z_{\text{eff}}(T,q)} dz_2 e^{-z_1 T} e^{-z_2 T} \Delta_0(z_1, z_2, q) + \Pi_{\text{power}}(T, q) \equiv \Gamma_{\text{dual}}(T, q, z_{\text{eff}}(T, q)). \]

We call the r.h.s. of (5.3) and (5.4) the dual correlators \( \Pi_{\text{dual}}(T, z_{\text{eff}}^I(T)) \) and \( \Gamma_{\text{dual}}(T, q, z_{\text{eff}}(T, q)) \), respectively. Let us notice that the dual correlators have both an explicit dependence on \( T \) and an implicit dependence on \( T \) via \( z_{\text{eff}} \).

As the consequence of (5.4), \( \Pi_{\text{power}}(T) = \Gamma_{\text{power}}(T, q = 0) \). It is natural to set

\[ z_{\text{eff}}^I(T) = z_{\text{eff}}(T, q = 0). \]  

Then, due to the Ward identity (4.14), the relations (5.3) and (5.4) yield the correct normalization of the form factor \( F_8(q = 0) = 1 \), as required by current conservation.

We treat the expressions (5.3) and (5.4) as the definitions of the exact \( T \)- and \( q \)-dependent effective continuum thresholds \( z_{\text{eff}}(T, q) \) and \( z_{\text{eff}}^I(T) \) corresponding to the true ground-state parameters on the l.h.s. The full \( T \)- and \( q \)-dependences of \( z_{\text{eff}}(T, q) \) can be obtained by solving Eqs. (5.3) and (5.4) for the known exact bound-state parameters \( R_8 \) and \( F_8(q) \) and the exact power expansions \( \Pi_{\text{power}}(T) \) and \( \Gamma_{\text{power}}(T, q) \). In the HO model this can be easily done numerically. Without loss of generality we set \( m = \omega \) and show the corresponding results in Fig. 3. Obviously, the effective continuum threshold does depend sizeably on both \( T \) and \( q \). Now, a good or a bad extraction of the ground-state parameters depends on our capacity to find a reasonable approximation to the exact effective continuum threshold.

Before closing this Section, we would like to make a comment on the \( T \)-dependence of the effective continuum threshold and the analytic properites of the dual correlator.

Recall that a correlator in perturbation theory satisfies the standard dispersion representation in \( E \) with the cuts given by the quark diagrams. In the language of hadronic states, this correlator contains contributions of an infinite number of such states.

¹ The standard duality assumption may be formulated as follows: the contribution of higher hadron states is dual to the high-energy region of the free-quark diagrams. Therefore, excited states do not receive any contribution from power corrections. One may, of course, argue whether this assumption is physically relevant: it would be perhaps more natural to relate to the excited states also high-energy contribution of diagrams containing the confinement interaction, like those corresponding to \( \Gamma_2 \). This would, however, require a detailed knowledge of the confining potential.
Fig. 3: The effective continuum threshold $z_{\text{eff}}(T, q)$ for the 3-point function, obtained by solving numerically Eq. (5.4) using the exact bound-state parameters $R_g$ and $F_g(q)$ as well as the exact power expansion $\Gamma_{\text{power}}(T, q)$, versus the Euclidean time $T$ at fixed values of the momentum transfer $q$ (a) and versus $q$ at fixed values of $T$ (b). In (a) the vertical dashed lines identify the fiducial range in $T$ (see text), while the solid lines are linear fits of $z_{\text{eff}}(T, q)$ in the fiducial range.

The dual correlator is a hand-made object and its analytic properties are very much different: the dual correlator should reproduce the contribution of a single ground state only, so it should have a single pole in $E$ and no cuts. Equivalently, the Borel-transformed dual correlator should contain only single exponential $\exp(-E_g T)$. Obviously, this may happen only if the effective threshold has a complicated dependence on $T$, since the spectral densities of the dual correlator and the perturbative correlator coincide.

Therefore, the dependence of the effective threshold on $T$ is its inherent property required by the analytic properties of the dual correlator.

6. NUMERICAL ANALYSIS

Let us now consider a restricted problem: assume that we know exactly the energy of the ground state, $E_g$. Our goal is to determine the decay constant and the form factor of this state from the sum rules (5.3) and (5.4). This problem is similar to the realistic case of the $B$-meson observables: in this case one knows the mass of the state and attempts to calculate its characteristics.

To obtain theoretical estimates for ground-state parameters, we must perform the following steps:

First, according to [1] we should determine the Borel window (or the fiducial range), where according to the sum-rule philosophy the method may be applied to the extraction of the ground-state parameters: (i) the lower boundary of the $T$-window is found from the requirement that the ground state gives a sizable (we require more than 50%) contribution to the correlator; and (ii) the upper boundary of the $T$-window is obtained from the requirement that the truncated OPE gives a good (we require better than 1%) approximation to the exact correlator.

Second, we must choose a criterion to fix our approximation for the effective continuum threshold $z_{\text{eff}}(T, q)$ and obtain in this way our sum-rule estimates for hadron observables.

Third, we should define the way to obtain the band of values which contains the actual value with 100% probability and a flat probability distribution, in other words, define the way to obtain systematic errors of the hadron parameter. Obviously, this is a highly nontrivial point.

The standard procedure adopted by sum-rule practitioners is to assume a $T$-independent effective continuum threshold. The quantity may be then either chosen as a $q$-independent constant or adjusted for any value of $q$, separately.

The variation of the extracted form factor in the window is conventionally treated as the systematic error of the ground-state parameter. It should be recalled that in QCD this is a matter of belief: it is not possible to prove that the interval obtained in this way indeed contains the true value.

In a series of recent publications we have demonstrated that in many cases these standard criteria fail: the actual parameters of the ground state turn out to lie beyond the range predicted by the sum-rule procedures. In [4] we have shown this for the extraction of the ground-state decay constant from the two-point function; in [5, 6] we have given examples of the form factor at specific values of momentum transfers, for which the standard criteria (stability in the window, deviation of the energy of the cut correlator from the ground-state energy in the window) suggest an accurate extraction of the form factor, whereas in practice the actual error turns out to be much larger. Now, we
are going to investigate whether improvements may be obtained by releasing the requirement of the \( T \)-independent effective continuum threshold and by imposing other criteria than Borel stability for obtaining the error estimates.

In this work we discuss three different Ansätze for the effective continuum threshold:

\[
\begin{align*}
    z_{\text{eff}}(T, q) &\approx z^C_0(q), \quad (6.1) \\
    z_{\text{eff}}(T, q) &\approx z^L_0(q) + z^I_1(q) \omega T, \quad (6.2) \\
    z_{\text{eff}}(T, q) &\approx z^Q_0(q) + z^Q_1(q) \omega T + z^Q_2(q) \omega^2 T^2. \quad (6.3)
\end{align*}
\]

At each value of \( q \) we fix the unknown parameters on the r.h.s of Eqs. (6.1)–(6.3) in the following way: we define the dual energy, \( E_{\text{dual}}(T, q) \), as

\[
E_{\text{dual}}(T, q) = -\frac{d}{dT} \log \Gamma_{\text{dual}}(T, q, z_{\text{eff}}(T, q)), \quad (6.4)
\]

where \( \Gamma_{\text{dual}}(T, q, z_{\text{eff}}) \) is the r.h.s. of Eq. (5.4) calculated using the approximations (6.1)–(6.3) for \( z_{\text{eff}}(T, q) \). Let us emphasize that the implicit dependence on \( T \) via \( z_{\text{eff}} \) is crucial for the calculation of the energy: if the exact effective continuum threshold has a sizeable dependence on \( T \), neglecting this dependence leads to a completely wrong energy, which we later tune to the exact known value. This is, in fact, the main source of error in the sum-rule predictions for hadron observables.

Next, we calculate \( E_{\text{dual}}(T, q) \) at several values of \( T = T_i \) \((i = 1, \ldots, N)\) chosen uniformly in the fiducial range. Finally, we minimize the squared difference between the dual energy \( E_{\text{dual}}(T, q) \) and the exact value \( E_{\text{g}} \):

\[
\chi^2 = \frac{1}{N} \sum_{i=1}^{N} [E_{\text{dual}}(T_i, q) - E_{\text{g}}]^2. \quad (6.5)
\]

A. Decay constant

Let us start with \( R_{\text{g}} \), the square of the decay constant. The standard procedures for this case were discussed in detail in [3]. The main results of [3] may be summarized as follows: in spite of the fact that the numerical value of the extracted decay constant turns out to be not far from the exact value (see also the discussion in [14]), the standard procedures fail to produce realistic error estimates: namely, the known true value lies outside the range obtained from the standard sum-rule analysis.

Fig. 4 shows the results obtained by allowing for a \( T \)-dependent threshold and tuning its parameters according to (6.3): one can see three approximations for \( z^H_{\text{eff}}(T) \) obtained by minimizing the function (6.5) for

\[
E_{\text{dual}}(T) = -\frac{d}{dT} \log \Pi_{\text{dual}}(T, z^H_{\text{eff}}(T)), \quad (6.6)
\]

\( \Pi_{\text{dual}}(T, z^H_{\text{eff}}) \) being the r.h.s. of (5.3), and the corresponding \( R_{\text{dual}}(T)/R_{\text{g}} \). The extraction of \( R \) is presented for three cases where a different number of power corrections — three, four, and infinite (i.e., exact power corrections) — in \( \Pi_{\text{OPPE}} \) are taken into account.

The case of the exact power corrections is presented as an illustration: we extract the ground-state parameters from the correlator by applying the sum-rule machinery in the window \( 0.7 \leq \omega T \leq 1.2 \) (although in this case, of course, the parameters may be extracted directly from the large-\( T \) behaviour of this correlator).

In all cases one can see an obvious improvement when the linear Ansatz \( z^L_{\text{eff}}(T) \) instead of the constant \( z^C_{\text{eff}} \) is used. Going beyond the linear approximation and allowing for the quadratic function \( z^Q_{\text{eff}}(T) \), however, does not lead to further improvement in the realistic cases of three and four power corrections in \( \Pi_{\text{OPPE}} \). This effect is just the reflection of the fact that the ground-state parameter may be extracted from the correlator only with a limited accuracy, even if the ground-state mass is known precisely (see also the detailed discussion in [3]). The same situation occurs for the form factor in Section 6.13.

B. Form factor

The standard sum-rule analysis of the ground-state form factor was presented in [3]. We have given there an explicit example of the sum-rule extraction of the form factor at a specific value of the momentum transfer where the method clearly fails in the following sense: the true value of the form factor turned out to lie well beyond the interval obtained
of the window. However, to be in line with the realistic situation where only a limited number of power corrections in H_{\text{OPE}}(T)$: $N = 3$ (first row), $N = 4$ (second row), and $N = \infty$ (third row). First column: the constant, linear, and quadratic approximations for the exact effective threshold $z_0^{\text{eff}}(T)$ obtained by minimizing (5.3). Second column: the corresponding $E_{\text{dual}}(T)/E_g$. Third column: the corresponding $R_{\text{dual}}(T)/R_g$. Red (dotted): constant $z_0^{\text{eff}}$; blue (dashed): linear $z_0^{\text{eff}}(T)$; green (solid): quadratic $z_0^{\text{eff}}(T)$. The vertical lines indicate the boundaries of the window.

by the standard sum-rule procedures. Moreover, the actual errors in the case of the form factor were shown to be much larger than those for the case of the decay constant.

We now apply a $T$-dependent Ansatz for the effective continuum threshold to extract the form factor. Recall that because of current conservation, the form factor $F(q)$ should obey the absolute normalization $F(q = 0) = 1$. We therefore require $z_0^{\text{eff}}(T) = z_0(T, q = 0)$: then at $q = 0$ the r.h.s. of Eq. (5.4) reproduces the r.h.s. of Eq. (5.3) and the form factor is automatically properly normalized. Therefore, the form factor extracted from the sum rule at small momentum transfers is anyway not far from its true value. Of real interest is the extraction of the form factor at the intermediate momentum transfers $q/\omega \approx 1/2$.

In the HO model we know all power corrections exactly, therefore, we have no limitation on the upper boundary of the window. However, to be in line with the realistic situation where only a limited number of power corrections is available, we define the window to be $0.7 \lesssim \omega T \lesssim 1.2$ (see Fig. 2).

The results for the form factor $F(q)$ obtained from the dual correlator by optimizing the parameters of the three Ansätze (6.1–6.3) according to (6.5) are shown in Figs. 5 and 6. For a $T$-independent approximation (6.1), the minimization of $\chi^2$ (6.5) leads to $z_0^C(T)$ for which the dual energy $E_{\text{dual}}(T, q)$ differs from $E_g$ by less than 1% and the dual form factor $F_{\text{dual}}(q)$ turns out to be practically $T$-independent in the whole fiducial range. Such a stability, usually referred to as the Borel stability, is often (erroneously) claimed to be the way to control the accuracy of the extracted form factor. From Fig. 5 it is clear, however, that the actual error of the extracted form factor turns out to be much larger than the variation of the form factor in the fiducial range of $T$. Moreover, the $T$-independent Ansatz is applicable only for not very large $q$: for $q \gtrsim 1.7 \omega$ it fails to reproduce the ground-state energy in the fiducial range.

For a $T$-dependent Ansatz (6.2) for $z_{\text{eff}}(T, q)$ extends the range of the momentum transfers where the form factor can be extracted from the sum rule with a reasonable accuracy. Note that the exact effective continuum threshold of the HO model can be well approximated by a linear function of $T$ in the whole fiducial range, see Fig. 3(a). Nevertheless, this does not mean that the minimization of (6.5) finds the exact effective continuum threshold and leads to the exact form factor: the deviation of the extracted form factor from the exact one amounts to a few percent for $q \lesssim 2\omega$ and increases dramatically for $q \gtrsim 2\omega$, see Fig. 6. The dramatic increase of the error at $q \gtrsim 2\omega$ is directly
Fig. 5: The extraction of the ground-state form factor at $q/\omega = 0.5$ (first row), $q/\omega = 1.5$ (second row), and $q/\omega = 2$ (third row). First column: the effective continuum threshold as found by the fitting procedure (6.5); second column: the fitted dual energy $E_{dual}(T, q)/E_g$; third column: the corresponding form factor ratio $F_{dual}(T, q)/F_g(q)$. Dashed black line: exact $z_{eff}$; full circles (red): constant $z_{eff}$; empty squares (blue): linear $z_{eff}(T)$; full diamonds (green): quadratic $z_{eff}(T)$.

Fig. 6: The ratio $F_{dual}(q)/F_g(q)$ of the form factor $F(q)$ extracted from the sum rule (5.4), using different approximations for $z_{eff}(T, q)$, and the exact ground-state form factor $F_g(q)$, given by Eq. (2.5), versus the momentum transfer $q$. The dots, squares and diamonds correspond, respectively, to the results obtained using a constant (6.1), linear (6.2) and quadratic (6.3) approximation for the $T$-dependence of $z_{eff}(T, q)$. 
related to the fact that the contribution of the ground state to the correlator decreases rapidly with \( q \) in the given \( T \)-window \( 0.7 \leq \omega T \leq 1.2 \) (see Fig. 1). Let us emphasize that the actual error of the extracted form factor turns out to be much larger than the variation of the form factor in the window, see Fig. 5.

One may try to go further and to consider the quadratic Ansatz (6.3). From Fig. 6 it is clear that the quadratic Ansatz leads to certain instabilities in the extracted value of the form factor and does not, in general, improve the actual accuracy of the form factor extraction. This is not strange: such a behaviour just reflects the fact that the sum-rule extraction of the ground-state parameters can be performed only with a limited accuracy, which has been known since the initial SVZ paper [1]. It should be therefore clear that there is no way to get further improvement in the accuracy of the extracted form factor by increasing the degree of the polynomial approximation of \( z_{\text{eff}}(T, q) \).

Nevertheless, we have seen a clear improvement in the outcome of the extraction procedure as one goes beyond the assumption of a \( T \)-independent effective continuum threshold: first, the actual accuracy turns out to be (much) better; second, the \( T \)-dependent Ansatz allows one to extract the form factor in a broader range of the momentum transfer.

The crucial question for the application of sum rules to the bound-state form factors is how to understand the actual accuracy of the ground-state parameter extracted from the sum rule.

(i) Obviously, the Borel stability does not guarantee the good extraction of the ground-state parameter and the variation of the extracted ground-state parameter in the window does not provide a realistic error estimate.

(ii) It should be understood that even a very accurate reproduction of the ground-state energy in the window does not lead to equivalently accurate extraction of the ground-state parameters. This is rather unpleasant since the deviation of the dual energy from the known ground-state energy is the only visible characteristic which can be controlled in the realistic cases. What really matters for the extraction of the bound-state parameters is the deviation of the fitted effective threshold from the exact effective threshold which, however, in the realistic cases remains unknown.

In the HO model, a realistic error estimate of the accuracy in a wide range of values of \( q \) may be obtained by comparing to each other the form factor values extracted by assuming the linear and quadratic Ans"atze for the effective continuum threshold (6.2) and (6.3). Whether this feature persists in QCD is an interesting and important issue to be addressed in the future.

7. CONCLUSIONS

We studied the extraction of the ground-state form factor from the vacuum-to-vacuum correlator in the exactly solvable harmonic-oscillator model applying the standard procedures of the method of QCD sum rules. Let us summarize the main messages of our analysis:

- The knowledge of the correlator in a limited range of relatively small Euclidean times \( T \) (that is, large Borel masses) is not sufficient for the determination of the ground-state parameters. In addition to the OPE for the relevant correlator, one needs an independent criterion for fixing the effective continuum threshold.

- Assuming a \( T \)-independent (i.e., a Borel-parameter independent) effective continuum threshold, the error of the extracted form factor \( F(T, q) \) turns out to be typically much larger than (i) the error of the description of the exact correlator \( \Gamma \) by the truncated OPE \( \Gamma_{\text{OPE}} \) and (ii) the variation of \( F(T, q) \) in the fiducial range of \( T \) (i.e., the Borel window). As the result, the actual value of the hadron form factor may lie far outside the range covered by the sum-rule estimate \( F(T, q) \) within the Borel window of \( T \). Therefore, the variation of the hadron form factor (as well as other hadron parameters) within the Borel window cannot be used as an estimate of its systematic error. The latter point is of particular relevance for the practical applications of sum rules in QCD, since the Borel stability is usually (erroneously) believed to control the accuracy and the reliability of the extracted ground-state parameter.

- In the cases where the ground-state mass is known (e.g., experimentally measured), the actual accuracy of the sum-rule analysis may be considerably improved by allowing for a \( T \)-dependent effective continuum threshold and finding its parameters by minimizing the deviation of the energy of the dual correlator from the known value of the ground-state energy, Eq. (6.5).

In the HO model, this procedure was shown to yield clear improvements in the extracted values of the decay constant and the form factor.

Moreover, in the HO model the deviation between the hadron parameter values obtained by using different Ansätze for \( z_{\text{eff}} \) gives de facto a realistic error estimate. This was observed for both the decay constant and the form factor.
Unfortunately, it remains impossible to construct the band of values which may be proven to contain the actual form factor. In this sense, the method of sum rules is not able to provide rigorous error estimates. Nevertheless, the application of the new procedures formulated in this paper to hadron form factors in QCD seems very promising with respect to improving the actual accuracy of the method.
