In this letter we show that for observables which involve the measurement of weak charge in final states in hadronic collisions, the standard parton model picture breaks down at scales well above the weak scale due to non-factorizable electroweak corrections at leading order in the power expansion. This implies that the resummation of these factorization-violating logarithms, which start at order $\alpha_s^2 \alpha_s^3 \log^4(Q^2/M_H^2)$, cannot be accomplished solely by following standard DGLAP evolution equations; other techniques will be needed to systematically sum large logarithms.

I. INTRODUCTION

It is a remarkable fact that one can make a prediction, within a systematic expansion, for a class of scattering cross sections between hadrons undergoing hard collisions. The proton represents a strongly coupled system composed of highly virtual entangled constituents, and yet when probed at short distances all of these complications can be neatly packaged, for sufficiently inclusive observables, into a parton distribution function (PDF), $f_{i/P}(x, \mu)$, which depends upon the light-cone momentum fraction $x$ carried by the parton and renormalization (or factorization) scale $\mu$.

These PDFs determine the probability to find a parton of type $i$ within the proton with a given momentum fraction $x$. Many hadronic cross sections can then be predicted in terms of a convolution of these PDFs with a quark-level scattering cross section. For instance, a standard hadronic process is Drell-Yan (DY), $PP \rightarrow l^+l^- + X$, the cross section for which can be written as a factorized convolution [1,2],

$$\sigma_{HH'} = \sum_{ij} f_{i/H}(\mu) \otimes f_{j/H'}(\mu) \otimes \tilde{\sigma}_{ij \rightarrow l^+l^- + X}(\mu), \quad (1)$$

where $\tilde{\sigma}_{ij \rightarrow l^+l^- + X}$ is the inclusive cross section for the partonic reaction, in which partons $i$ and $j$ produce a lepton pair and a hadronic state $X$, while $f_{i/H}$ and $f_{j/H'}$ are the PDFs (for partons of type $i$ and $j$, respectively) for the incoming anti-collinear hadrons. This result is valid to leading order in an expansion in $\Lambda_{QCD}/Q$, where $\Lambda_{QCD} \sim 1$ GeV is the QCD scale and $Q$ is the scale of the hard cross section. The long distance physics is contained in $f_{i/H}$ and $f_{j/H'}$, and is in general incalculable analytically, due to the confining nature of QCD. We have made the renormalization group (RG) scale ($\mu$) dependence in this formula explicit because it reminds us that for our predictions to be accurate (systematic in any perturbative expansion) we must sum logs of the ratio of scales in the theory (in this case $\log(Q^2/\Lambda_{QCD}^2)$). To resum these logs one solves the renormalization group equation (in this context called the DGLAP equation [3]) so that each function in the convolutions sits at its “natural scale,” so we choose, $\sigma(\mu = Q)$ and $f_{i/H}(\xi, \mu = \Lambda_{QCD})$. This RG component of the parton model can be ruined when the factorized form [1] is violated for certain observables, as we now discuss.

II. GLAUBER'S AND FACTORIZATION VIOLATION IN QCD

Equation (1) is what is known as a factorization theorem and can be elegantly described within the confines of effective field theory (EFT), namely by soft-collinear effective theory (SCET), where one splits the fields into a set of modes, each with its own unique momentum region [4]. In the EFT, the stress energy tensor of the leading order action can be written as a sum over the relevant modes,

$$T_{\text{EFT}}^{\mu\nu} = T_n^{\mu\nu} + T_\alpha^{\mu\nu} + T_s^{\mu\nu}. \quad (2)$$

Here $n(\bar{n})$ stands for “(anti-)collinear” modes with light-cone momenta scaling as $k_n^\mu \sim (1, \lambda^2, \lambda)$, $k_{\bar{n}}^\mu \sim (\lambda^2, 1, \lambda)$, respectively, while “soft” modes scale as $k_s^\mu \sim (\lambda, \lambda, \lambda)$. For this notation we have decomposed momenta into $(p^+, p^-, p_z)$. $\lambda$ is the power counting parameter, defined as $\lambda \equiv \Lambda_{IR}/Q$, where $\Lambda_{IR}$ is the relevant low scale in the theory, which depends upon the observable. As previously noted, for DY, $\Lambda_{IR} \sim \Lambda_{QCD}$, as long as the masses ($m$) of all the particles in the loops are order $\Lambda_{QCD}$. The hard scattering of top or bottom quarks is treated by introducing the notion of the top/bottom quark content of the proton, that is, introducing PDFs for these massive quarks. Because $m_t,b \gg \Lambda_{QCD}$ the massive quark content of the proton is produced in perturbation theory via the splitting of collinear partons, which is only sensible at RG scales well above the mass of the quark. Note that although these PDFs are produced in perturbation theory, their effects become order one when $\alpha_s \log(Q^2/m^2) \sim 1$.

For scales above $m$, the quarks are taken to be massless, and the relevant infrared (IR) scale becomes $m$ so that $\lambda \sim m/Q$. This change in the power counting will be relevant once we discuss electroweak corrections. This splitting of degrees of freedom in the EFT leads to a tensor product Hilbert space

$$|\psi\rangle = |\psi\rangle_{n} \otimes |\psi\rangle_{\bar{n}} \otimes |\psi\rangle_{s}, \quad (3)$$

where $n(\bar{n})$ stands for “(anti-)collinear” modes with light-cone momenta scaling as $k_n^\mu \sim (1, \lambda^2, \lambda)$, $k_{\bar{n}}^\mu \sim (\lambda^2, 1, \lambda)$, respectively, while “soft” modes scale as $k_s^\mu \sim (\lambda, \lambda, \lambda)$. For this notation we have decomposed momenta into $(p^+, p^-, p_z)$. $\lambda$ is the power counting parameter, defined as $\lambda \equiv \Lambda_{IR}/Q$, where $\Lambda_{IR}$ is the relevant low scale in the theory, which depends upon the observable. As previously noted, for DY, $\Lambda_{IR} \sim \Lambda_{QCD}$, as long as the masses ($m$) of all the particles in the loops are order $\Lambda_{QCD}$. The hard scattering of top or bottom quarks is treated by introducing the notion of the top/bottom quark content of the proton, that is, introducing PDFs for these massive quarks. Because $m_t,b \gg \Lambda_{QCD}$ the massive quark content of the proton is produced in perturbation theory via the splitting of collinear partons, which is only sensible at RG scales well above the mass of the quark. Note that although these PDFs are produced in perturbation theory, their effects become order one when $\alpha_s \log(Q^2/m^2) \sim 1$.

For scales above $m$, the quarks are taken to be massless, and the relevant infrared (IR) scale becomes $m$ so that $\lambda \sim m/Q$. This change in the power counting will be relevant once we discuss electroweak corrections. This splitting of degrees of freedom in the EFT leads to a tensor product Hilbert space

$$|\psi\rangle = |\psi\rangle_{n} \otimes |\psi\rangle_{\bar{n}} \otimes |\psi\rangle_{s}, \quad (3)$$
which facilitates factorization proofs of Ref. [5]. The PDFs, \( f \), are matrix elements of (anti-)collinear operators, so it is manifest that the various modes are completely detached as necessitated by Eq. (2). The only interactions between various modes are in the hard scattering kernel \( \sigma \), where perturbation theory is valid due to asymptotic freedom.

A natural question one should ask about Eq. (1) is why don’t interactions between spectator particles (i.e. the infinite complement to the active parton, which undergoes the hard scattering, within the proton) play a role in determining the cross section? One would think that as long as soft gluons can be exchanged between spectator and active partons, or between spectators from each proton (as shown in Fig. 1) the factorized form (1) should be violated. Indeed, a simple one-loop calculation of the cross section shows that in fact such (“Glauber gluon”) contributions do exist at leading power in \( \Lambda/Q \). Yet, the result in Eq. (1) describes the data remarkably well, a fact which seems to negate the existence of such soft exchanges.

The reason Eq. (1) properly describes DY is that in this process the Glauber contributions will cancel provided one freely integrates over the difference between the transverse momenta of the near-forward final state jets as proven in Ref. [2]. In SCET, the inclusion of Glauber gluons in hard scattering processes was introduced in [2]. This work introduced an operator formalism that can be used to treat Glaubers systematically in the power expansion, and rederived the aforementioned, sufficient condition for factorization violation, but did not prove the sufficient conditions (as done in [2]) for Glauber cancellation.

When determining whether or not the Glaubers contribute to a given observable we must be sure that their effects are not already being accounted for in the canonical result [1]. That is, Eq. (1) contains a set of Wilson lines in the PDF, which account for some fraction of the long distance physics and we must not be fooled by (unphysical) Feynman diagrams into thinking that the Glaubers are not already contained in these Wilson lines.

In SCET, it has been shown [7] that the Glauber exchange between active and spectator quarks can be absorbed into the aforementioned Wilson lines, and thus are benign. However, it was also shown that the same cannot be said for Glaubers exchanged between spectators. As mentioned above, for sufficiently inclusive observables, these Glauber gluons cancel in the final cross section. This cancellation occurs order by order, diagram by diagram, after the sum over all cuts of a diagram [2]. If we consider the pure Glauber exchange between spectators (as in Fig. 1), to all orders, then the Drell-Yan amplitude is, in impact parameter \( (b) \) space, proportional to a phase \( \phi \):

$$
M \sim \int d^2 b \rho e^{-i \Delta p \cdot b} E(b, q) e^{i \phi(b)} ,
$$

with \( \Delta p = (p_{2\perp} - p_{1\perp})/2 \) and \( q = -(p_{1\perp} + p_{2\perp})/2 \). The phase,

$$
\phi(b) = -T_1^4 \otimes T_5^4 g^2(\mu) \frac{\Gamma(\gamma) \left( \frac{\mu b_\perp e^{i \gamma}}{2} \right)^{2\epsilon}}{4\pi} \Delta p
$$

is a matrix in color space with \( T_1^4 \) and \( T_5^4 \) being the color matrix generators that commute with each other, and act on particle 1 and 2, respectively. The \( \Gamma(\gamma) \) infrared divergence is akin to the usual Coulomb phase. It is noted that the phase in the squared amplitude vanishes only, as previously noted, if we perform the integral over \( \Delta p \) over the full range of integration.

An example of an observable where the Glaubers are not expected to cancel is beam thrust, where one weights the final state transverse momentum distribution \( \Delta p \), and we should not expect to (and cannot) fit the data using the canonical formalism that leads to (1). We will use the term “Kinematics Factorization Violation” (KFV) when factorization is violated by restricting the kinematics, to differentiate this scenario from the new one, which will be introduced below.

### III. ELECTROWEAK GLAUBERS

Suppose we wish to calculate electroweak (EW) corrections to the DY process. While at \( Q \) below the weak scale, EW contributions are suppressed by powers of \( \Lambda_R^2/M_W^2 \), for \( Q > M_W \) they become relevant especially given the fact that electroweak corrections generate double logs of the form \( \alpha_W \log^2(Q^2/M_W^2) \), as discussed further below. Thus, there has been considerable effort [9, 10] to resum EW corrections for LHC and future collider predictions. The question arises as to whether or not we should expect that, by including PDFs for all (massive) standard model particles, the parton model paradigm will still hold. That is, can we calculate EW contributions using Eq. (1) for arbitrarily large \( Q \)?

When addressing this question we begin by noting that

---

1. Recently a proof of the cancellation of Glaubers in double parton scattering was given in [6].
2. Here we are following the EFT methodology. In [2] the modes are not separated in terms of different fields.
the weak gauge group is not in the confining phase\footnote{The lack of clear distinction between Higgs/Coulomb and confining phase is of no relevance here.}. The significance of this distinction lies in the fact that we observe final state EW charge. Indeed, DY in this sense is an exclusive observable since we measure leptons, which are now “active partons” in the final state. Furthermore, protons are charged in the weak sector and, as such, even completely inclusive quantities will be sensitive to the gauge-boson mass as the KLN theorem is violated \cite{11,12}, and as a consequence the cross sections will include the aforementioned (Sudakov) double logarithms.

To study electroweak Glauber effects, we will continue with our canonical example of Drell-Yan. Above the weak scale, we allow for PDFs for all of the Standard Model (SM) particles, and the relevant IR scale becomes $M_W$ as in the case of massive quarks discussed above. In addition, we must generalize our factorization theorem (1) to account for the fact that the proton is not an electroweak singlet, which again enhances the sensitivity to the IR double logarithms of the masses. As a result, the factorization theorem changes in two important ways. Firstly, the electroweak charge of the proton implies that the bilinear operators which compose the PDF need no longer be a SM gauge singlet.

Recall the QCD PDF that takes on the general form
\[
f^{(QCD)}_{i/p}(\xi) = \langle p| \int dy^- e^{iyp^+} y^- O_i(y^-) \Gamma W[y^-, 0] O_i(0) |p\rangle,
\]
where $O$ is any (QCD) parton field and $W$ is the aforementioned Wilson line, which renders the bilinear gauge invariant, and $\Gamma$ is a spin tensor. The generalization of this form to the full standard model gauge group must allow for bilinears that are not $SU(2)$ singlets. For instance, in addition to singlet PDFs we allow for a triplet of the form
\[
f^{(SM)}_{i/p}a(\xi) = \langle p| \int dy^- e^{iyp^+} y^- \tilde{O}_i(y^-) \tilde{\Gamma} W[y^-, \infty] 
\times \Gamma \tau^a \tilde{W}[\infty, 0] \tilde{\Gamma}_i(0) |p\rangle,
\]
where $\tilde{W}$ are electroweak Wilson lines and the QCD Wilson line has been suppressed. Furthermore, the operators get modified such that
\[
\tilde{O} = SO,
\]
where $S$ is a Wilson line composed of soft gauge fields, which cancel in the case of singlet operator\footnote{This cancellation occurs as a consequence of the need to multipole expand the soft fields \cite{13} so that the Wilson lines cancel as a consequence of unitarity $S^a S = 1$.} The existence of the soft Wilson lines changes the way the logarithms are resummed in that the EW sector now contains rapidity logarithms \cite{13}. Secondly, since in DY we identify the leptons in the final state, and we are interested in resumming electroweak logs, we must account for final state cascades. The measurement of the final state isospin implies that we must include fragmentation functions $F_{i/j}$ in the convolution of Eq. (1), which give the probability of finding a given parton type $j$ in the jet created by a mother parton of type $i$. As in the case of the PDF, these fragmentation functions must also be generalized to allow for non-singlet operators \cite{15,16,17}.

While we have had to modify Eq. (1), generalizing the factorization theorem to the standard model, the notion of a PDF in the context of the parton model of hadrons persists, in that the collinear partons in the two sectors are decoupled, as long as we can still prove that the Glauber contributions cancel. In the next section, we will detail an example where they do not.

\section{IV. ELECTROWEAK FACTORIZATION VIOLATION}

The measurement of final state isospin charge imperils the EW Glauber cancellation by its exclusive nature. We have noted that the QCD Glauber exchanges cancel upon summing over cuts. However, given that we are measuring the charge of the final state, it is clear that the cancellation can become ineffective since some diagrams will not contribute for fixed-charge final states. Another complication arises, \textit{e.g.} in DY, as the final states are now charged ($SU(2)$), and we must consider a new set Glauber exchanges, \textit{i.e.} those between spectators and active final states. An explicit calculation shows that Glauber integral is not sensitive to the collinear direction of the active parton. The underlying reason for this independence is the following identity
\[
n' \cdot p = \frac{n \cdot n'}{2} - \frac{n' \cdot n}{2} - n' \cdot p - n \cdot p = \frac{n \cdot n'}{2} - n \cdot p + O(\lambda).
\]
Here $n/n'$ defines the direction of the spectator and $n'$ is the direction of the final state active parton. The residual $n'$ dependence will cancel due to reparametrization invariance \cite{19}.

The consequences of this independence are two-fold. If the current is a singlet then the Glaubers will cancel explicitly in the sum over all possible Glauber insertions, as shown in Fig. 2\footnote{FIG. 2. Glauber exchange between spectators and active collinear partons in the final state. For a singlet current, the sum over Glauber graphs vanishes.}. For a non-singlet current, as might be expected, this cancellation no longer
occurs directly. However, in this case, the final state active/spectator Glauber exchanges can be absorbed into collinear (EW) Wilson lines, which now accompany the current. To see this, we note that the Wilson line for each collinear sector\( (\text{say } n \text{ sector}) \) is in fact generated by summing over \( n \) collinear emissions from all other collinear sectors \( (n', \bar{n}, \bar{n}') \). The interactions between the \( n \)-spectator and all the other active partons (including the final state active partons) are contained within the zero-bin of the corresponding interactions of the \( W \), Wilson line and the \( n \)-spectator as illustrated by Fig. 3, leaving the factorization theorem unscathed.\footnote{When the Glaubers are absorbed in this way, it fixes the direction of the Wilson line, i.e., whether it stretches to \( \pm \infty \).}

The generalization to the EW gauge group does not alter the fact that spectator-spectator Glauber exchange persists. However, if we are measuring final state charge of the spectators, the cancellation is obstructed. For instance, suppose we are measuring top quark production rate which includes (the dominant) near forward direction, suppose we are measuring top quark production of the spectators, the cancellation is obstructed. For in-

We perform the loop integrals we find

$$
\frac{d\sigma}{d\Pi_{t+t^{-}}} = \sum_{i+j} B_{i}^j \otimes \bar{B}_{i}^j \otimes \sigma_{i+j\rightarrow t+t^{-}} + X, \quad (10)
$$

where \( \Pi_{t+t^{-}} \) denotes whatever explicit measurement made on the leptons, and

$$
B_{i}^j (\xi) = \langle p | \int dy e^{i\xi p \cdot y} O_{i}^j (y^{-}) W[y^{-}, 0] \times \Gamma | t + X \rangle (t + X | O_{i}(0) | p), \quad (11)
$$

while \( t \) and \( \bar{t} \) are replaced in \( \bar{B}_{i}^j \). This is essentially the same as the PDF defined in Eq. 6 with the exception that the final state for this matrix element is no longer inclusive. If we, in fact, remove the requirement of top quarks in the final state, then we are once again fully inclusive over the spectators and recover Eq. 4.

However, Eq. 10 is not correct, as the cancellation between the two diagrams shown in Fig. 4 is blocked by the difference in the isospin charges which weight the diagrams. This prevents writing the observable as a simple convolution of two two-parton operators, like the \( B_{i} \) above. Rather, the correct factorization theorem will require a new four-parton operator that involves active and spectator partons from both protons \( 20 \). This type of “Flavor Factorization Violation” (FFV) is distinct from KFV, and will arise for any observable where a particle ID is made unless a cut is made enforcing large \( p_{t} \gg M_{W} \). The contribution of these factorization violating diagrams is given by

$$
\text{Im} M_{4t} \sim \sum_{i} P_{qg}(x) P_{qg}(y) \int d^{2} \vec{p}_{t} d^{2}\bar{\vec{p}}_{t} \frac{d^{2} \vec{p}_{t}}{1 + M_{W}^{2} / p_{t}^{2}} \frac{d^{2} \bar{\vec{p}}_{t}}{1 + M_{W}^{2} / \bar{\vec{p}}_{t}^{2}} \times \frac{1}{(\vec{p}_{t} - \vec{l}_{t}) \cdot (\bar{\vec{p}}_{t} - \bar{\vec{l}}_{t}) (\vec{p}_{t} + \vec{l}_{t}) \cdot (\bar{\vec{p}}_{t} + \bar{\vec{l}}_{t})} \times \frac{1}{(\vec{p}_{t} + \vec{l}_{t})^{2} + m_{t}^{2} (\bar{\vec{p}}_{t} + \bar{\vec{l}}_{t})^{2} + m_{t}^{2}} \delta(xy - Q^{2} / \hat{s}), \quad (12)
$$

where \( P_{qg} \) is the quark-gluon splitting function and \( x \), \( y \) are the momentum fractions of the incoming gluons. Performing the loop integrals we find

$$
\text{Im} M_{4t} \sim \alpha_{s}^{2} \alpha_{W}^{2} \log^{4}(M_{W}^{2} / Q^{2}), \quad (13)
$$

where we have set the RG scale \( \mu \) to the scale of hard scattering and \( m_{q} \sim M_{W} \). Note that these logarithms cannot be resummed by the canonical running of the PDF, as expected, since the Glaubers talk between the two proton jets. This dimensionless correction factor in Eq. 13 already reaches 0.1 for \( Q \sim 10 \text{ TeV} \). The detailed quantitative study of these contributions is beyond the scope of this work, but this basic estimate shows that the numerical importance of this effect need not be small.

For the case when all the hard interaction currents have no weak charge (e.g. \( P + P \rightarrow \text{jets} \)), again assuming we measure some weak charge in the final state, we expect a cancellation between diagrams with the topology

\footnote{Some authors prefer to reserve the term factorization violation to refer only to quantities participating at the hard vertex. We use it here though, to refer to the fact that radiation exchanged between different collinear sectors cannot be written as a Wilson line.}
of Figs. [4(a)] and [4(b)] which will eliminate the leading quartic logarithmic terms. There will be mass dependent terms at leading order in the power expansion since $m_t \sim M_W$ that lead to asymptotic logs of the form

$$\alpha_s^2 \alpha_w^2 \left(M_t^2/M_W^2\right) \log(M_W^2/Q^2).$$

(14)

All the logarithms obtained here via the electroweak Glauber exchange are not associated with the BFKL [22] logarithms usually associated with near-forward scattering (rapidity logs). Rather these are renormalization group logarithms that are resummed by augmenting the space of four parton operators [20]. There will be BFKL running as well, that will be subleading to [13].

V. CONCLUSIONS

We have shown that the parton model picture, where a systematic calculation of a hard scattering cross section follows from a factorization theorem involving PDFs, no longer holds when directly extended to the EW sector and applied to EW observables in proton scattering. In the EW case, a new mechanism for factorization violation arises when final state isospin is measured for states with $y \gtrsim 1, p_t \gtrsim 100$ GeV, as the requisite cancellation is obstructed due to the dearth of allowed cuts. As a result, one may not simply add leptonic and EW gauge-boson PDFs (as put forward in [10]) and accurately sum all of the EW logarithms using DGLAP physics.

This violation, while numerically small at the weak scale, will become logarithmically enhanced for $Q \gg M_W$, and will become relevant for a myriad of interesting observables, including multi-Higgs production. Moreover, the factorization-violating logarithms are not summed by the BFKL equations nor by the DGLAP equation, but will need to be treated within a new formalism that will be presented elsewhere [20]. Furthermore, we see that for certain processes, like forward top quark production, novel operators beyond the usual PDF framework are required. From a field theoretic standpoint this implies that, as we push the energy frontier beyond the weak scale, various other theoretical techniques, beyond the now-textbook DGLAP material, will need to be harnessed/developed, at least for a class of relevant observables.
