ABSTRACT

Aims. We aim for a better understanding of gas properties in the circum-nuclear disk (CND) region of the nearby gas-rich Seyfert 2 galaxy NGC 1068. We focus on line identification and the basic physical parameters estimation of molecular gas in the CND region.

Methods. We used the IRAM 30 m telescope to conduct deep millimeter spectroscopy observations toward the center of NGC 1068.

Results. Thirty-two lines were detected in this galaxy, 15 lines of which were detected for the first time. With a sensitivity better by about a factor of 4 than observations in the literature for this source at 3 mm band, we detected several weak lines for the first time in this source, such as lines from CH\(_3\)C\(_2\)H\(_2\), CH\(_3\)OCH\(_3\), and HC\(_5\)O\(_4\). Column densities of these molecules were estimated based on line emissions. Some marginal detections in the literature, such as HN\(_3\)C(1–0), were confirmed. CH\(_3\)OCH\(_3\) was detected for the first time in external galaxies. Lines from several carbon chain molecules and shock-related molecules were also detected in this source.

Key words. ISM: molecules – galaxies: ISM – galaxies: individual: NGC 1068 – galaxies: nuclei – galaxies: active

1. Introduction

As cold molecular clouds are opaque to the visible and UV radiation in the Milky Way and other galaxies, observations of molecular rotational transitions at millimeter wavelength are important to study the interstellar medium (ISM; Omont 2007). As a tracer of total molecular gas in galaxies, low-J CO transitions have been observed in more than one thousand galaxies (Sanders et al. 1991; Young & Scoville 1991; Kennicutt 1998), while lines of molecules with high dipole moments, such as HCN (1–0), have also been detected as dense gas tracers in many galaxies (Gao & Solomon 2004; Liu et al. 2015).

Multiple line observations, especially with lines of different molecules (Usero et al. 2004), can provide useful constraints on the gas properties. A broadband line survey toward nearby galaxies is a powerful tool for such a study, which has been performed for M82 (Aladro et al. 2011) and Arp 157 (Davis et al. 2013) at the 3 mm band, NGC 253 at the 2 mm band (Martín et al. 2006), and Arp 220 at the 1 mm band (Martín et al. 2011).

As a prototypical Seyfert 2 galaxy with starburst at a distance of 14.4 Mpc (1″ = 72 pc, Bland-Hawthorn et al. 1997), NGC 1068 was observed at radio (Greenhill et al. 1996), millimeter (Schinnerer et al. 2000), infrared (Jaffe et al. 2004), optical (Antonucci & Miller 1985), UV (Antonucci et al. 1994), and X-ray (Kinkhabwala et al. 2002). High spatial resolution CO (1–0) observations show two molecular spiral arms with a diameter of ~40″ and a northern half-bar, while a CO (2–1) map reveals a nuclear ring with two bright knots in the CND region (Schinnerer et al. 2000). The dense gas fraction as traced by HCN (1–0) (Tacconi et al. 1994; Helfer & Blitz 1995) and CS (2–1) (Tacconi et al. 1997; Takano et al. 2014) in the nuclear region is higher than the two arms. Observations of CO (3–2) (Krips et al. 2011; Tsai et al. 2012; García-Burillo et al. 2014) showed that the difference of molecular gas temperatures between the nuclear region and the two arms was not as large as that of densities. Dozens of molecular lines at millimeter wavelength were detected at CND with single-dish observations (Usero et al. 2004; Nakajima et al. 2011, 2013; Aladro et al. 2013). Moreover, several molecules were detected and resolved toward NGC 1068 with interferometers in the past few years (Tosaki et al. 2017; Kelly et al. 2017; Furuya & Taniguchi 2016; Izumi et al. 2016; Inamishii et al. 2016; Nakajima et al. 2015; Viti et al. 2014; Takano et al. 2014; García-Burillo et al. 2014, 2016). The molecular gas in the CND region was denser and hotter than that in the starburst ring, while chemical properties in the two regions were also different (Viti et al. 2014). The highest molecular gas temperature was higher than 150 K, and the gas density was above 10\(^5\) cm\(^{-3}\) in the CND region (Viti et al. 2014). The distribution of different species of molecules were also different: CO isotopic species, for instance, were enhanced in the starburst ring, while the shock/dust related molecules were enhanced in the CND region (Nakajima et al. 2015). The spatially resolved observations showed that the CND region was a complex dynamical system. For instance, the east and west...
we discuss the properties of carbon chain molecules and shock- and the main results of the detected lines are provided in Sect. 3, follows: in Sect. 2 we present observations and data reduction, as well as on the basic physical parameter estimation. The detailed of the CND.

dots were dominated by a fast shock and a slower shock (Kelly et al. 2017), while the dust torus also showed complex kinematics (García-Burillo et al. 2016). Gas inflow was driven by a past minor merger (Furuya & Taniguchi 2016), while the outflow was AGN driven (García-Burillo et al. 2014). We conducted a deeper survey of millimeter lines toward the CND region of NGC 1068 with the IRAM 30 m telescope, with the goal to quantify the gas properties in the CND. Compared to previous single-dish observations, our data probe weaker transition lines, which could place more constraints on the physical and chemistry properties of the CND.

In this paper, we focus on the transition line identification as well as on the basic physical parameter estimation. The detailed analysis for the physical and chemical properties and discussion will be the focus of a future paper. This paper is organized as follows: in Sect. 2 we present observations and data reduction, and the main results of the detected lines are provided in Sect. 3, we discuss the properties of carbon chain molecules and shock-related molecules in Sect. 4, and give a brief summary in Sect. 5.

### 2. Observations and data reduction

The observations toward the center of NGC 1068 (RA: 02:42:40.70 Dec: –00:00:48.0 J2000) were made at the end of December 2011, using the IRAM 30 m telescope at Pico Veleta, Spain\(^1\). The Eight Mixer Receiver (EMIR) with dual-polarization and the Fourier Transform Spectrometers (FTS) backend, which gave the frequency channel spacing of 195 kHz and 8 GHz instantaneous frequency coverage per sideband and per polarization, were used. The standard wobbler-switching mode with a ±120° offset at 0.5 Hz beam throwing was used for the observations. Pointing was checked about every two hours with nearby strong millimeter-emitting quasi-stellar objects. The typical system temperatures were 110 K at the 3 mm band, 142 K at the 2 mm band, and 172–223 K at the 1 mm band. We read out each spectrum every 12 min, which had an effective on-source time of about 5 min.

The molecular line intensities indicated in the antenna temperature (\(T_A\)) were converted into the main beam temperature (\(T_{mb}\)) using \(T_{mb} = T_A \times \frac{\theta_{mb}}{\theta_T^2}\), with the parameters of each band listed in Table 1. The data were reduced with the CLASS software of the GILDAS package\(^2\). We inspected each spectrum visually, and qualified spectra by comparing the measured noise and the theoretical noise before and after a few times of the boxcar smoothing. None of the spectra was discarded during the qualification. We subtracted linear baselines for all spectra and averaged them with time weighting for each frequency coverage, which is listed in Table 1. We identified each line by referring to frequencies from the National Institute of Standards and Technology (NIST) database recommended rest frequencies for observed interstellar molecular microwave transitions\(^3\).

\(^1\) Based on observations carried out with the IRAM 30 m telescope. IRAM is supported by INSU/CNRS (France), MPG (Germany), and IGN (Spain).

### Table 1. Band parameters.

| Band range  | \(E^*\) | \(F_{sl}\) | \(B_{sl}\) | HPBW | Spatial resolution |
|-------------|--------|--------|--------|------|-------------------|
| GHz         | GHz    | %      | %      |      | kpc               |
| 84.0–92.2   | 86     | 95     | 81     | 29.3–26.9 | 2.1–1.9          |
| 162.2–166.2 | 145    | 93     | 74     | 15.2–14.8 | 1.0              |
| 211.6–219.4 | 210    | 94     | 63     | 11.6–11.2 | 0.8              |
| 217.2–227.4 | 210    | 94     | 63     | 11.3–10.8 | 0.8              |
| 237.7–245.5 | 230    | 92     | 58     | 10.3–10.0 | 0.7              |

Notes. \(E^*\) means equivalent frequency, where \(\text{HPBW (deg)} = \frac{\text{MBBW (arcsec)}}{\cos\theta}\). \(F_{sl}\) and \(B_{sl}\) were taken from the web site of the IRAM 30 m. http://www.iram.es/IRAMES/mainWiki/Iram30mEfficiencies
3. Results

Thirty-two lines, including 31 lines from 26 molecules and 1 hydrogen recombination line, were detected toward the nuclear region of NGC 1068. The detected C$_2$H (1–0) (ethyl) lines show a double-component profile instead of six hyperfine lines due to line broadening, which were counted as one line in our list. All the detected lines are listed in Table 2, including the information of velocity-integrated fluxes, line center velocities, and line widths, which were obtained from Gaussian fitting with CLASS. Fifteen lines were first detected in NGC 1068, which are noted in Table 2 in boldface.

CH$_3$OCH$_3$ was tentatively detected as the first detection of this molecule in galaxies. The molecules, which have previously been detected in other galaxies but were not detected for the first time in NGC 1068, were HC$^{13}$O$^+$, CH$_3$CH$=CH_2$, and H$_2$CO. Some molecules have previously been detected in NGC 1068 with other transitions, but the lines were first detected, such as SiO (5–4), H$_2$CO, HNCO (11–0–1), HC$_3$N (18–17), SO (5–6–4), and SO (5–4–3).

Four molecules are detected with multiple transitions, which are SiO (2–1) and (5–4), HNCO(4$_{0,4}$–3$_{0,3}$) and (11–0,11–10,10), HC$_3$N(10–9) and (18–17), and CH$_3$CN (5$_{0,4}$–4$_{0,3}$) and (12$_{0,11}$–11$_{0,10}$). Lines of isotopic molecules are detected for four groups of molecules, which are HCO$^+$ (1–0), H$^{13}$CO$^+$ (1–0), HC$^{18}$O$^+$ (1–0); HCN (1–0), H$^{13}$CN (1–0); HNC (1–0), HN$^{13}$C (1–0); $^{13}$CO (2–1), and C$^{18}$O (2–1). The transition lines for three types of isotomers are detected, which are H$^{13}$CN (1–0) and HN$^{13}$C (1–0); HCN (1–0) and HNC (1–0), and HCO$^+$ (1–0) and HOCS$^+$ (1–0). The spectrum of each line is shown in Figs. 1 to 6.

We estimated column densities of the five newly detected species (CH$_3$CH$=CH_2$, CH$_3$OCH$_3$, H$_2$CO, SO$_2$, and HC$^{18}$O$^+$) toward the center of NGC 1068 under local thermal equilibrium (LTE) assumption with the following equation:

$$N = \frac{8\pi k v^2 Q(T_{ex})}{h c^3} A_{ij} g_i \epsilon_{ij}/kT_{ex} C_t \int \tau_M b dv,$$

where $k$ is the Boltzmann constant in J K$^{-1}$, $v$ is the rest frequency of the transition line in Hz, $Q(T_{ex})$ is the partition function, $h$ is the Planck constant in J s, $c$ is the light speed in cm s$^{-1}$, $A_{ij}$ is the spontaneous emission coefficient in s$^{-1}$, $g_i$ is the total degeneracy of upper energy level, $E_u/k$ is the upper
level energy in K, \( C_r \) is the factor of optical depth correction, and \( \int T_M \, d\nu \) is the detected transition line integrated intensity in K cm s\(^{-1}\). The values of \( Q(T_{\text{ex}}) \), \( A_{\text{dd}} \), \( g_{\text{d}} \), and \( E_0/k \) were taken from the Cologne Database for Molecular Spectroscopy (CDMS) catalog\(^4\) and splat catalogue astronomical spectroscopy database\(^5\). To simplify the problem and facilitate calculation, we assumed an average source size of 4\('\) for the beam dilution correction for all these five species. We used the rotational temperature of 10 ± 5 K for four species (\( \text{CH}_3\text{CCH}, \text{CH}_2\text{OCH}_3, \text{H}_2\text{CO}, \) and \( \text{HC}^{18}\text{O}^+ \)); the explanation in Aladro et al. (2013), and 60 ± 30 K for \( \text{SO}_2 \), which is equal to the rotational temperature of SO we derived. Since the \( \text{C}_2\text{H}(1–0) \) hyperfine transition lines are mainly optically thin (see Sect. 4 for details), the optical depth correction was not considered. The column densities of the five newly detected species are listed in Table 3.

The information of individual molecules are listed below:

- Methyl alcohol – \( \text{CH}_3\text{OH} \)
  \( \text{CH}_3\text{OH}(5_{1,3}–4_{0,2}) \) was detected at the rest frequency of 84.521 GHz in NGC 1068 (see Fig. 1). A detailed discussion of this line as a new mega-maser molecule has been presented in Wang et al. (2014a).
- Oxomethyl – \( \text{HCO} \) and silicon monoxide – \( \text{SiO} \)
  HCO(1_{0,1}–0_{0,0}) was detected at the rest frequency of 86.671 GHz in this source, blended with \( \text{H}^{13}\text{CO}^+ (1–0) \) and \( \text{SiO} (2–1, v = 0) \) at the rest frequencies of 86.754 GHz and 86.847 GHz, respectively (Fig. 1). We used three-component Gaussian fitting to deblend the lines. Our results are consistent with the detection of this line reported in the literature

was detected at the rest frequency of 86.340 GHz (Fig. 3) in this source, which has been reported in Nakajima et al. (2011) and Aladro et al. (2013). Detailed discussions of the isotopic ratio and optical depth have been presented in Wang et al. (2014b).

- Isotopic hydrogen isocyanide – HNC and HN\(^{13}\)C

HNC (1–0) was detected at the rest frequency of 90.664 GHz, which is consistent with the results in the literature (Aladro et al. 2013). We found that the line profile was almost symmetrical, but we were unable to fit it with a single Gaussian profile, as shown in Fig. 3. HN\(^{13}\)C (1–0) was detected at the rest frequency of 87.091 GHz (see Fig. 4). Detailed discussions of HN\(^{13}\)C have been presented in Wang et al. (2014b).

- Ethynyl – \(^{13}\)C\(_2\)H

\(^{13}\)C\(_2\)H (1–0) was detected with six hyperfine components, which is consistent with the results in the literature (Aladro et al. 2013). We mark the hyperfine lines from 1 to 6 in Fig. 4. However, we were unable to fit the six hyperfine lines with multiple Gaussian components because of line broadening. Thus, we counted the six hyperfine lines of \(^{13}\)C\(_2\)H as one detected line, and the integrated intensity is 7.94 \pm 0.053 K km s\(^{-1}\).

- Isocyanic acid – HNCO

HNCO (11,0,11–10,0,10) was detected at the rest frequency of 241.774 GHz. HNCO (4,0,4–3,0,3) was also detected at the rest frequency of 87.925 GHz, which has been reported in the literature (García-Burillo et al. 2010; Aladro et al. 2013). Our result for HNCO (4,0,4–3,0,3) agrees well with García-Burillo et al. (2010), while Aladro et al. (2013) gave a much lower line flux than ours. The flux in our detection is 674.8 \pm 44.6 mK km s\(^{-1}\), while it was 100 mK km s\(^{-1}\) in Aladro et al. (2013). HNCO (11,0,11–10,0,10) overlaid with HNCO (4,0,4–3,0,3) is presented in Fig. 4.

- Cyanooctethylene – HC\(_3\)N

We detected HC\(_3\)N (10–9) and HC\(_3\)N (18–17) at the rest frequencies of 90.979 GHz and 163.753 GHz, respectively. The results of our detection for HC\(_3\)N (10–9) are consistent with that in Aladro et al. (2013). HC\(_3\)N (10–9) overlaid with HC\(_3\)N (18–17) is presented in Fig. 4. The fluxes of HC\(_3\)N (18–17) and (10–9) are \(3.90 \pm 0.15\) Jy km s\(^{-1}\) and \(2.34 \pm 0.44\) Jy km s\(^{-1}\), respectively.

- Dimethyl ether – CH\(_3\)OCH\(_3\)

CH\(_3\)OCH\(_3\) (3,2–3,1) was marginally detected at the rest frequency of 91.477 GHz (Fig. 5). This is the first detection of this molecule in external galaxies. It has up to nine atoms and is the heaviest molecule detected so far with (sub-)millimeter transitions in such sources. Since it was a marginal detection, we only list an upper limit of the column density with \(N_{\text{CH}_3\text{OCH}_3} \leq (2.3 \pm 1.4) \times 10^{15}\) cm\(^{-2}\).

- Isotopic carbon monoxides – \(^{13}\)CO and C\(^{15}\)O

\(^{13}\)CO (2–1), SO (5–4), \(^{13}\)CO (2–1), and CH\(_3\)CN (12–11) were detected at the rest frequency of 219.560 GHz, 219.949 GHz, 220.399 GHz, and 220.747 GHz, respectively. These are blended (Fig. 5). Our results for \(^ {13}\)CO (2–1) are consistent with that in the literature (Israel 2009). In order to better show the weak lines, we first used four-component Gaussian fitting for the spectrum and then subtracted the two strong lines (\(^ {13}\)CO (2–1) and C\(^{15}\)O (2–1)). Then, we used a two-component Gaussian to fit the residual spectrum and we obtained the information for SO (5–4) and CH\(_3\)CN (12–11). SO (5–4) was also detected at the rest frequency of 215.221 GHz. It is shown in Fig. 5 with (5–4) overlaid.

4. Discussion

4.1. Carbon-chain molecules

Several carbon-chain molecules, including C\(_2\)H, c-C\(_3\)H\(_2\), HC\(_3\)N, CH\(_3\)CCH, CH\(_3\)CN, and CH\(_3\)OCH\(_3\), were detected in NGC 1068. C\(_2\)H and c-C\(_3\)H\(_2\) are the most abundant molecules with two and three carbon atoms in the interstellar medium, and they both have a tight correlation with the star-forming regions behind diffuse and translucent clouds (Lucas & Liszt 2000; Gerin et al. 2011). C\(_2\)H was first detected by Tucker et al. (1974) in the Milky Way, while it was first detected in the extragalactic source M 82 by Henkel et al. (1988). Meier & Turner (2005) reported a high-resolution C\(_2\)H (1–0) observation toward the nuclear region of nearby galaxy IC 342, which showed that C\(_2\)H was abundant in the central region and might be affected by photodissociation region (PDR) chemistry. The authors suggested that C\(_2\)H is probably abundant where C\(^{+}\) and FUV photons are profuse (Meier & Turner 2005).
Owing to the line broadening, the six hyperfine components of \( \text{C}_2\text{H}(1-0) \) were in two groups. Two-component Gaussian fitting (Jiang et al. 2011) was used to obtain the line ratio of the two groups, which gave fluxes of 5.6 and 2.4 K km s\(^{-1}\), respectively. The relative optical depth ratio probably is 4.25 : 41.67 : 20.75 : 20.75 : 8.33 : 4.25 for the six hyperfine transition lines (Tucker et al. 1974). When we assume that the six lines have the same excitation temperature and filling factors, the relative intensity ratio of the two groups is

\[
(1 - e^{-4.25\tau_0}) + (1 - e^{-41.67\tau_0}) + (1 - e^{-20.75\tau_0})
\]

\[
(1 - e^{-20.75\tau_0}) + (1 - e^{-8.33\tau_0}) + (1 - e^{-4.25\tau_0}),
\]

which decreases from about 2.2 to 1.0 with increasing \( \tau_0 \). The measured ratio of the two groups is 2.25 ± 0.08, which means that the \( \text{C}_2\text{H}(1-0) \) lines are mainly optical thin.

\( \text{C}_2\text{H} \) and \( \text{c-C}_3\text{H}_2 \) are abundant in the diffuse and translucent matter (Lucas & Liszt 2000) and interstellar matter in the Galactic plane (Gerin et al. 2011). The emission line ratio of \( \text{C}_2\text{H}(1-0) \) to \( \text{c-C}_3\text{H}_2 (2_1,2-1_0,1) \) in NGC 1068 is 6.78 ± 0.34, close to the value of 7.13 ± 5.49 in the star-forming regions of M 51 (Watanabe et al. 2014). Future high-resolution observations of \( \text{C}_2\text{H} \) and \( \text{c-C}_3\text{H}_2 \) lines will be useful to understand \( \text{C}_2\text{H} \) and \( \text{c-C}_3\text{H}_2 \) chemistry in the nuclear region and the spiral arms of NGC 1068.

Figure 2 shows spectra of \( \text{CH}_2\text{CCH} (5_0-4_0) \) at the rest frequency of 85.457 GHz together with \( \text{c-C}_3\text{H}_2 (2_1,2-1_0,1) \) at the rest frequency of 85.339 GHz. \( \text{c-C}_3\text{H}_2 \) (cyclopropenylidene). With the designation \( \text{c} - \), which means cyclic, it is the most stable molecule and has three carbon atoms and two hydrogen atoms (Spezzano et al. 2012). The rotational spectral line of \( \text{c-C}_3\text{H}_2 \) was first detected in Sgr B2 (Thaddeus et al. 1985), while the extragalactic \( \text{c-C}_3\text{H}_2 \) was first detected in M 82 (Mauersberger et al. 1991), which was used as a good tracer of a PDR in galaxies (Martín et al. 2006).

Interstellar methylacetylene (\( \text{CH}_3\text{CCH} \)) was first detected with the \( J = 5_0-4_0 \) transition in Sgr B2 (Snyder & Buhl 1973), and \( \text{CH}_3\text{CN} \) (methyl cyanide) was first detected with \( J = 6-5 \), also in Sgr B2 (Snyder & Buhl 1973), while \( \text{CH}_2\text{CCH} \) and \( \text{CH}_3\text{CN} \) were first detected in extragalactic sources in M 82 and NGC 253 with multiple transitions (Mauersberger et al. 1991). As second-generation molecules, the formation of \( \text{CH}_3\text{CN} \) was generally interpreted with the grain mantle evaporation scenario, such as for IRAS 16293-2422 (Bottinelli et al. 2004).

The line ratio \( R \), defined as \( \frac{I_{4_{11}}} {I_{5_{00}}} \), is 0.84 ± 0.27 in NGC 1068, but is greater than 2 in M 82 and is 0.33 ± 0.07 in NGC 253 (Mauersberger et al. 1991). These results imply that the properties of large carbon chain molecules, such as \( \text{CH}_3\text{CCH} \) and \( \text{CH}_3\text{CN} \), in the CND of NGC 1068 are more similar to the properties in NGC 253 than to the properties in M 82.

\( \text{CH}_3\text{OCH}_3 \) (dimethyl), which was first detected in Orion with multiple transitions (Snyder et al. 1974), was also detected in NGC 1068. The high column density of \( \text{CH}_3\text{OCH}_3 \) indicates that molecules with a methyl radical are enhanced in the CND region of NGC 1068, which makes this region an ideal candidate to search for large carbon molecules.

With deep observations toward the CND of NGC 1068, emissions from molecules with up to nine atoms have been detected, which means that these large molecules can survive in the CND regions even near AGN with a strong X-ray radiation field. Further high-resolution observations toward such sources with ALMA can better determine the chemical networks of these molecules, which is important for the formation of larger molecules and for comparing the astrochemical conditions of molecular gas near AGN with star-forming regions in galaxies.

### 4.2. Shock-related molecules

High spatial resolution of \( \text{CO}(3-2) \) observation suggests a massive molecular outflow, which was considered as a bow-shock in the molecular disk (García-Burillo et al. 2014). Lines from three shock-related molecules (\( \text{SiO} \), \( \text{SO} \), and \( \text{HNC} \)) in the CND of NGC 1068 were detected with our observations. With different transitions of the fast-shock tracer \( \text{SiO} \), the 2–1 line shows a broader line width than the 5–4 line (see Fig. 4 and Table 2), which means that part of the shocked gas was not dense enough to reach the excitation conditions of \( \text{SiO}(5–4) \). On the other hand, \( \text{HNC} \), which is thought to be a tracer of slow shocks or to originate from a dense region without a shock, shows similar line widths of the 11–10 and 4–3 transitions (see Fig. 15 and Table 2). High-resolution observations of the \( \text{SiO} \) and \( \text{HNC} \) lines (García-Burillo et al. 2010; Kelly et al. 2017) show a clear difference between these tracers with different spatial distributions. Even though high-resolution observations with millimeter interferometers will be more powerful to distinguish the shock gas tracers in these galaxies, single-dish observations with multiple transitions will also be a useful tool to study the physical properties of shocked gas.

### 5. Summary

With deep millimeter line observations toward the nuclear region of NGC 1068 with the IRAM 30 m telescope, we detected 32 lines, 15 of which were first detected in NGC 1068. In particular, \( \text{CH}_3\text{OCH}_3 \) was first detected in galaxies. Several carbon chain molecules (\( \text{C}_2\text{H}_3 \), \( \text{c-C}_3\text{H}_2 \), \( \text{HC}_3\text{N} \), \( \text{CH}_3\text{CCH} \), \( \text{CH}_3\text{CN} \), and \( \text{CH}_3\text{OCH}_3 \)) were detected toward the nuclear region near the...
Based on the ratio of the $C_2H$ models for such molecular gas with a strong X-ray field, central AGN, which needs to be explained with more chemical complexity, has also been detected with multiple transitions with different line widths, which indicates that the shocked regions had complicated excitation conditions.
