INTRODUCTION

Thyroid hormones (THs) are essential for fetal and post-natal nervous system development and also play an important role in the maintenance of adult brain function. Of the two major THs, T4 (3,5,3′,5′-tetraiodo-l-thyronine) is classically viewed as an pro-hormone that must be converted to T3 (3,5,3’-tri-iodo-l-thyronine) via tissue-level deiodinases for biological activity. THs primarily mediate their effects by binding to thyroid hormone receptor (TR) isoforms, predominantly TRα1 and TRβ1, which are expressed in different tissues and exhibit distinctive roles in endocrinology. Notably, the ability to respond to T4 and to T3 differs for the two TR isoforms, with TRα1 generally more responsive to T4 than TRβ1. TRα1 is also the most abundantly expressed TR isoform in the brain, encompassing 70–80% of all TR expression in this tissue. Conversion of T4 into T3 via deiodinase 2 in astrocytes has been classically viewed as critical for generating local T3 for neurons. However, deiodinase-deficient mice do not exhibit obvious defectives in brain development or function. Considering that TRα1 is well-established as the predominant isoform in brain, and that TRα1 responds to both T3 and T4, we suggest T4 may play a more active role in brain physiology than has been previously accepted.

Keywords: T4 thyronine, T3 thyronine, thyroid hormone receptor, brain, coregulator, deiodinase 2

Thyroid hormones (THs) are synthesized by the thyroid gland and are critical regulatory molecules with important roles in vertebrate physiology and development, including fetal and post-natal nervous system development and the maintenance of adult brain function (1, 2). The TH requirement for development is most apparent in the central nervous system (CNS) where severe TH deficiency in fetal and neonatal periods results in cretinism, a disease characterized by mental retardation, deafness, and ataxia; these consequences are irreversible if not treated soon after birth (3–5). Additionally, untreated hypothyroidism in the adult is associated with severe intellectual defects, abnormal balance and defects in fine motor skills, spasticity, and deafness (6). Correcting TH deficiencies is critical for normal brain development and function.

THs primarily mediate their effects by binding to thyroid hormone receptors (TRs), members of the nuclear hormone receptor family (4, 7, 8). TRs bind to the DNA regulatory regions of target genes to activate or repress transcription through interactions with accessory proteins known as coregulators. There are two major THs, which bind to and activate TRs: T3 (3,5,3′-triiodo-l-thyronine) and T4 (3,5,3′,5′-tetraiodo-l-thyronine, also known as thyroxine). T4 differs from T3 by an additional iodine located at the 5′-position of the first thyroxine ring. T3 has been assumed to be the active form of TH, as T3 binds to TRs with a greater affinity than T4. In this model, T4 is thought to simply act as a pro-hormone, existing only to be circulated in the serum and converted at the tissue-level to T3 through an enzymatic reaction involving the removal of the 5′-iodine atom from T4 by local deiodinases (9, 10). Nonetheless, it is notable that most of the TH produced under normal conditions in the thyroid is secreted in the form of T4 and steady-state serum concentrations of T4 are many fold greater than those of T3 (11–14). Notably, iodine intake is important for the maintenance of both of these TH levels in circulation. In fact, during gestation and lactation in females, double the normal iodine intake is required to maintain adequate T3 and T4 in circulation to ensure normal fetal development (15, 16). Under conditions of low iodine intake, the serum T3/T4 ratio is somewhat increased reflecting the reduced abundance of iodine atoms (16). Although the ready availability of dietary iodized salt has largely eliminated these iodine deficiencies for school children in most developed countries today, these advances are often not adequate for pregnant and lactating women (17).

Indeed the primary TH crossing the adult blood–brain barrier (BBB) is believed to be T4; therefore, the adult brain may have access to sufficiently high levels of T4 to allow for direct binding to and transcriptional activation of TRs (18, 19). In fact, we know that both T4 and T3 binding by TRs lead to very similar structural changes in the receptor (12). Several reports have also shown that T4 exhibits non-genomic effects by interacting with integrin cell membrane receptors (20). These studies suggest that T4 might exhibit a greater role in physiology than merely acting as a pro-hormone. Therefore, the precise role of T4 as a pro-hormone and whether T4 might function directly as an active hormone in the CNS, remain incompletely answered questions.

T4 SYNTHESIS, TRANSPORT, AND AVAILABILITY IN THE BRAIN

Determining the effective cellular concentrations of T4 and T3 in the brain, or in any tissue, is difficult due to the complexities of TH synthesis, transport, and regulation. Vertebrates have developed multiple mechanisms to ensure delivery of appropriate levels of TH to peripheral tissues such as the brain. These include regulation of secretion of THs from the thyroid into serum (21, 22),
control of free versus bound levels of THs determined by reversible binding to serum-binding proteins (22), cell-specific expression of TH cell membrane transporters (23, 24), and finally intracellular deiodination of T4 to form T3 [(22, 25); Figure 1].

Transplacental TH transfer from maternal to fetal circulation is particularly important in vertebrate CNS development [reviewed by Ref. (26)] to ensure appropriate levels of TH are available to the fetus throughout development (16). Throughout the first trimester when TH levels are solely obtained through maternal transfer, free T4 levels are high in the fetus, similar to levels of biologically active T3 in adults, whereas fetal concentrations of T3 are at least 10× lower than T4 (16). Notably, T3 levels in the fetal cerebral cortex increase somewhat between 12 and 20 weeks PMA (post-menstrual age) when placental deiodinase 2 levels increase (see below), although maternal serum and 20 weeks PMA (post-menstrual age) when placental deiodinase 2 levels increase (see below), although maternal serum concentrations of T3 from circulating T4. However, we propose that T3 may also act directly on TRs to regulate gene transcription in neurons in the absence of deiodinase 2 conversion to T4.

**Figure 1** | Thyroid hormone synthesis. The thyroid gland makes both T4 and T3, although T3 predominates. The hypothalamus senses low TH in the circulation and responds by stimulating synthesis and secretion of TRH (thyroid releasing hormone), which in turn circulates and stimulates synthesis and secretion of TSH (thyroid stimulating hormone) by the pituitary. Circulating TSH then increases T4 and T3 production by the thyroid and ultimately in the circulation. Tissue-specific deiodinases (“DIO”) are expressed in peripheral tissues such as brain astrocytes to increase local concentrations of T3 from circulating T4. However, we propose that T3 may also act directly on TRs to regulate gene transcription in neurons in the absence of deiodinase 2 conversion to T4.

Outer ring 5′-monodeiodination via cell-specific deiodinases converts a small fraction of the normal serum T4 pool to T3 (10, 22). Deiodinase 2 is the primary enzyme responsible for intracellular conversion of T4 into T3 in most local tissues including brain, whereas deiodinase 1 is found primarily in the liver (25, 27). Deiodinase 2 is only expressed in selected cell types within the CNS: astrocytes and tanycytes. These are both glial cell-derived and are located in the hypothalamus (28–30). The other deiodinase enzyme expressed in the CNS is deiodinase 3, selectively expressed in neurons. Deiodinase 3 inactivates both T4 and T3 by inner ring deiodination to rT3 and T2 so as to down-regulate local TH concentrations and protect the neuron from supraphysiological levels of TH. Currently it is believed that astrocytes generate active T3 from circulating pro-hormone, T4, whereas neurons degrade both T4 and T3 to inactive rT3 and T2, respectively, and thereby regulate local TH availability within the brain. When levels of TH are low, deiodinase 2 levels in brain increase and contrastingly when there are high levels of TH, deiodinase 3 levels increase (19, 30, 31). This balancing act protects the brain from the detrimental effects of hyper- or hypothyroidism.

T3 concentrations equilibrate rapidly in peripheral tissues such as the liver and kidney but appear to take longer to equilibrate in the brain. In general, TH concentrations in the CNS are approximately 20% that of serum concentrations (32); this is likely due to the added complexity of TH transport across the BBB, which is comprised of the endothelial cells of brain capillaries surrounded by astrocyte end feet. To enter the brain, the THs cross the BBB of the choroidal plexus via the MCT8 or OATP1C1 TH transporters. T4 is thought to predominate in the CNS in preference to T3 as the majority of BBB TH transporters exhibit greater affinities for T4 transport [(19, 33); Figure 2]. As mentioned above, after T4 is taken up into astrocytes likely by OATP1C1, deiodinase 2 can in turn convert it locally to T3. Finally, the astrocyte-generated T3 can enter neuronal cells via the MCT8 transporter to bind and activate TRs. Therefore, it is intriguing that the T4-activating deiodinase is not expressed in the neurons themselves, where the relevant TRs are located, but in the astrocytes. T4 and/or T3 also enter the CNS directly via gaps in the end feet of the astrocytes, which do not completely cover the capillaries in contact with the interstitial spinal fluid (34).

**DIFFERENT TR ISOFORMS DIFFER IN THEIR ABILITY TO BIND TO T4**

Thyroid hormones bind TRs, ligand-regulated transcription factors, which bind to specific target DNA sequences and repress or activate target genes through the recruitment and release of accessory proteins. TRs contact their DNA-binding elements as protein dimers, heterodimerizing with another member of the nuclear receptor family, RXRs (primarily Retinoid X Receptors), or homodimerizing with themselves (35–39). TRs exhibit bimodal regulation, typically binding corepressors to repress transcription of target genes in the absence of TH, but releasing corepressors and recruiting coactivators to activate transcription of these “positive response” target genes in the presence of TH (40, 41). These corepressor and coactivator proteins alter the chromatin template or interact with the general transcription machinery to produce the appropriate transcriptional outputs. However, many TR target
Thyroid hormone receptors are encoded by two distinct genetic loci, denoted THRA and THRB, which are each expressed as alternatively spliced mRNAs to create additional receptor diversity [reviewed in Ref. (42)]. Two of the major TR isoforms are referred to as TRα1 and TRβ1; both bind TH and yet exhibit distinct biological roles [reviewed in Ref. (43)]. TRα1 is expressed early in embryonic development and then widely in adults whereas TRβ1 is expressed later in embryonic development and exhibits a more restricted tissue-expression pattern in adults (31, 44–49). Genetic disruption in mice of TRα1 or TRβ1 indicates that these isoforms have somewhat overlapping, yet distinct roles in normal physiology (45–47, 49, 50).

These two different TR isoforms differ in their ability to respond to T4, with TRα1 generally exhibiting a much stronger response to T4 than TRβ1. We suggest that different cell types may modulate their relative ability to respond to T4 versus T3 by altering the relative abundance of different coactivators and corepressors that have distinct responses to T4 and T3, raising the possibility that T4 may be able to function as a direct-acting hormone agonist with TRα1 (Amy C. Schroeder and Martin L. Privalsky, unpublished observations).

TRα1 EXPRESSION IN THE BRAIN

Notably, TRα1 encompasses 70–80% of all TR expression in the adult vertebrate brain (2) and TRα1 is present in nearly all neurons (51). Intriguingly, TRα1 is also the predominating TR isoform early in fetal brain development (detected by 8.1 weeks and increasing until 13.9 weeks post-menstrual age). Critical roles in CNS development are known to be mediated by TRα1 including TH-dependent oligodendrocyte differentiation (52). If TRα1 is inactivated, the number of mature oligodendrocytes after T3 treatment is decreased (52). The commitment of these cells as oligodendrocytes is therefore believed to be linked to cell-specific TRα1 expression while the availability of TH regulates the timing of differentiation (52). In fact, maturation of several cell types in the brain in development may depend on specific windows of TRα1 expression and involve a complicated interplay between TRs, THs, and coregulators (2). Additionally, TRα1 is known to exhibit important roles in later stages of neurodevelopment and its expression persists in adult neurons. Therefore, it is interesting that expression of the TRα1 isoform predominates in both fetal and in adult brain at the same times when free T4 levels appear to be at biologically active levels (16), suggesting windows in brain development may exist where T4 may act on TRα1.

DEIODINASE 2-DEFICIENT MICE EXHIBIT NORMAL CNS DEVELOPMENT AND FUNCTION

As noted above, deiodinase 2 expression does not overlap TR receptor expression in the brain. Deiodinase 2 is expressed instead in astrocytes whereas the TRs are expressed in neurons along with deiodinase 3 [(28, 29); Figure 2]. The current theory therefore suggests astrocytes are involved with T4 uptake from capillaries to subsequently generate a source of locally generated T3. Conversion of T4 into T3 via deiodinase 2 in astrocytes has been estimated to be...
produce as much as 80% of the T\textsubscript{3} bound to the TRs in the brain (18), suggesting astrocyte deiodinase 2 is important for generating local T\textsubscript{3} concentrations. Therefore, many argue that deiodinase 2 likely plays a critical role in developing brain by providing the necessary amount of T\textsubscript{3}. If this were in fact the case, one would predict the absence of deiodinase 2 would result in detrimental defects in CNS development similar to that seen in hypothryoidism.

However, the Galton lab produced a deiodinase 2-deficient and a deiodinase 2/deiodinase 1 dual-deficient mouse (KOs) without any evident defects in brain development or function (27, 53). The deiodinase KO mice demonstrated slightly elevated circulating T\textsubscript{4} and TSH levels, and normal thyroid-secretion of T\textsubscript{3} but no tissue-level production of T\textsubscript{3} from T\textsubscript{4} (27). Notably, these mice did not display any signs of hypothryoidism and have no gross physiological or behavioral abnormalities (27). The deiodinase KO was also combined with an MCT8 TH transporter knockout (54, 55); this combination resulted in minor neuronal defects mostly noted by decreased expression of genes in the neural cortex, which are usually positively regulated by T\textsubscript{3}, however, most neural development and function was normal. KO mice studies suggest that T\textsubscript{4} transport into the brain and local conversion of T\textsubscript{4} to T\textsubscript{3} in the brain are not essential for normal brain function in mice, and suggest that CNS T\textsubscript{3}-defects do not produce syndromes as severe as that seen in the hypothryoid mice (27).

Many suggest that there might be compensation in the deiodinase KO mice through the absorption of more T\textsubscript{3} directly from circulation via the MCT8 transporter in endothelial cells of the BBB, but it should be again noted that the parallel transporters such as OATP1C1 and OATP2 favor T\textsubscript{4} transport (56, 57) and it is unlikely that T\textsubscript{3} can be transported into the brain at rate equivalent to T\textsubscript{4} transport. We suggest that in the absence of available T\textsubscript{3}, T\textsubscript{4} can act as an active TH in the brain working on, most likely, TR\textalpha1. Interestingly, in the absence of deiodinase 1 and 2, positively regulated TH genes in the cerebral cortex remain unaffected but negatively regulated TH genes appear to be impaired in a way that parallel the hypothryoid mice (27, 58). Perhaps in the absence of deiodinase 2, T\textsubscript{4} can act as an active hormone in brain cells to activate positively regulated TH genes, but not to repress negatively regulated TH genes.

It should be noted that humans with MCT8 mutations display severe neurodevelopmental defects with psychomotor retardation and abnormal serum TH levels (57, 59)). Conversely, MCT8 KO mice mimic the human MCT8 mutations in their thyroid phenotype but display no obvious brain developmental defects (57, 59). It is therefore possible that the need for locally produced T\textsubscript{3}, and/or the presence of alternative T3-specific transporters, differ in mice and in humans (55).

TR COREGULATORS AND THE BRAIN

T\textsubscript{4} efficiently recruits many coactivators to TR\textalpha1, with certain well-established TR coactivators (SRC1 and TRAP220) exhibiting a T\textsubscript{4} response equal or near equal to that induced by T\textsubscript{3} (Amy C. Schroeder and Martin L. Privalsky, unpublished observations). SRC1 mRNA is expressed in many tissues during development including the CNS (60). TRAP220 is also expressed in the developing brain and is thought to play a regulatory role in the process of cell proliferation and differentiation, in learning, and in memory formation (61). The widespread expression of TRAP220 in the developing brain appears to parallel TR\textalpha1 expression. Therefore, CNS development correlates with a high level of expression of TR\textalpha1 together with TRAP220 and/or SRC1 and may provide an opportunity for T\textsubscript{4} to directly regulate gene transcription. CNS cell-specific differences in TR isoform and cofactor levels or function are likely to contribute to differences in T\textsubscript{3} hormone response and may suggest a means by which the T\textsubscript{4} sensitivity of a given CNS cell type can be regulated in response to internal or external signals.

A POSSIBLE DIRECT ROLE FOR T\textsubscript{4} IN BRAIN: ARE THERE CONTEXTS IN THE BRAIN IN WHICH T\textsubscript{4} IS A DIRECT-ACTING TR\textalpha1 AGONIST?

Several recent studies have led to the view that T\textsubscript{4} exhibits non-genomic roles that do not require conversion to T\textsubscript{3} (20) but which have not challenged the general view that T\textsubscript{3}, not T\textsubscript{4}, is the only direct, biologically relevant agonist for nuclear TR function. Our own experiments indicate that TR\textalpha1 has the potential to act as a dual sensor of both T\textsubscript{4} and T\textsubscript{3} (Amy C. Schroeder and Martin L. Privalsky, unpublished observations).

Although the effective concentration of T\textsubscript{4} in the brain is difficult to determine, it is plausible that T\textsubscript{4} levels are sufficient to induce activation of TR\textalpha1-regulated genes in the brain even in the absence of T\textsubscript{3}. We suggest that the normal mix of T\textsubscript{4} and T\textsubscript{3} in the brain may actually confer a mixed T\textsubscript{4}/T\textsubscript{3} transcription response mediated primarily by TR\textalpha1, together with a more pure T\textsubscript{3} response mediated primarily by TR\beta1. Notably, mice in which both deiodinase 1 and 2 have been genetically ablated, and thus lack astrocyte deiodinase conversion of T\textsubscript{4} to T\textsubscript{3}, display only very mild defects in their physiological with little to no neurological defects (27). If, as indicated by these knockouts, T\textsubscript{4} is not absolutely required in its traditional role as a pro-hormone, the dominance of T\textsubscript{4} to T\textsubscript{3} in the circulation and transport into the CNS may instead reflect a novel role of T\textsubscript{4} as a direct-acting hormone and this direct role may be helping to ameliorate the effects of the deiodinase knockouts in the CNS.

In conclusion, TH endocrinology in the CNS is tightly regulated at multiple tiers. Negative feedback loops in the hypothalamus and the pituitary control T\textsubscript{3} and T\textsubscript{4} output by the thyroid gland itself. Further, multiple phenomenon functions together to modulate the transport of circulating TH through the BBB, and multiple transporters act together to directly alter TH availability in the CNS itself. Additionally, conversion of intracellular T\textsubscript{4} into T\textsubscript{3} by deiodinase 2, inactivation of both T\textsubscript{3} and T\textsubscript{4} by deiodinase 3, and, the ability of different TR isoforms and different coregulators to respond directly to T\textsubscript{4} versus T\textsubscript{3} further regulate the CNS response to TH. Operating together, we propose these mechanisms serve to maintain proper endocrine homeostasis while permitting the CNS to respond to developmental and physiological needs.
