Abstract. Extensive programs of follow-up observations of hard X-ray selected sources have unambiguously revealed that the sources of the X-ray background are characterized by an extremely large dispersion in their optical magnitude and spectroscopic classification. Here we present the results of an attempt to understand the nature of the observed variety using a simple prescription for their optical to X-ray energy distribution.

Key words: X-rays, Surveys

1. Introduction

Thanks to the capabilities of the detectors onboard Chandra and XMM–Newton the X-ray sky is now probed down to flux limits where the bulk of the hard X-ray background is resolved into single sources. The accuracy in the positioning of hard (2–10 keV) X-ray sources is more than an order of magnitude better than that achieved by ASCA and BeppoSAX in the same energy range. One of the most interesting consequences of this enormous improvement is the possibility to identify a relatively large number of hard X-ray sources characterized by broad band properties which are significantly different from those of conventional AGN selected in the optical and soft X-ray bands. Although there are compelling theoretical and observational evidences which suggest that the large majority of the hard X-ray sources are obscured AGN, the origin of such a broad variety in their multiwavelength properties is still far to be understood.

2. The $f_X/f_{\text{opt}}$ diagnostic

It is well known that various classes of X-ray emitters are characterized by different values of their X-ray to optical flux ratio (see fig. 1 in Maccacaro et al. 1988). For a given X-ray energy range and the R band filter the following relation holds: $\log f_X/f_{\text{opt}} = \log f_X + 5.5 + R/2.5$. The large majority of spectroscopically identified AGN in both ROSAT (e.g. Hasinger et al. 1998) and ASCA (Akiyama et al. 2000) surveys fall within $-1 < \log(f_X/f_{\text{opt}}) < 1$. Extensive optical follow-up observations of hard X-ray sources discovered by deep and medium deep Chandra and XMM–Newton surveys confirm this trend to fainter X-ray fluxes and, at the same time, show evidence of a relatively large number of sources which deviate from $\log(f_X/f_{\text{opt}}) = 0 \pm 1$ (Fig. 1). For the purposes of the present paper it is convenient to divide the “outliers” in two groups. The first includes sources that are X-ray weak for their R band magnitudes ($\log f_X/f_{\text{opt}} \simeq -1$); the second, sources that are optically faint (sometimes below the limits of deep optical images) and relatively X-ray bright ($\log f_X/f_{\text{opt}} > 1$). In the following we refer to both classes of sources as unconventional AGN.

The identification breakdown of the sources in the first group is a mixed bag including emission line galaxies and apparently normal galaxies (see Alexander et al. this volume). A sizeable fraction of the latter, named XBONG (X-ray Bright Optically Normal Galaxies; Comastri et al. 2002b), are particularly intriguing being characterized by an absorption dominated optical spectrum and AGN–like hard X-ray luminosities ($L_{2–10} \simeq 10^{42–43}$ erg s$^{-1}$). They are found at moderately low redshift, $z < 1$; Hornschemeier et al. 2001, Barger et al. 2002). The average value of their $\log f_X/f_{\text{opt}}$ distribution is around $-1$ with a large dispersion (Fig. 3). An attempt to deeply investigate their nature through a multiwavelength approach suggests that the putative AGN responsible for the hard X-ray emission is completely hidden at longer wavelengths (Comastri et al. 2002a).

The sources characterized by high values of $f_X/f_{\text{opt}}$ are even less understood. The spectroscopic identification of these objects is already challenging the capabilities of 8–10 m optical telescopes calling for the next generation of

Fig. 1. The 2–10 keV flux versus the R band magnitude for six different surveys as labeled. From top left the HELLAS2XMM survey (Baldi et al. 2002), The XMM survey in the Lockman Hole (Mainieri et al. 2002); the ELAIS deep Chandra survey (Manners et al. 2002), the combination of a few medium deep Chandra surveys (Barger et al. 2001), The Chandra Deep Field South (Giacconi et al. 2002) and the Chandra Deep Field North (Brandt et al. 2001). The upper (lower) solid line corresponds to log \( \frac{f_X}{f_{opt}} = 1 \) (–1). The shaded area represents the region occupied by conventional AGN (e.g. quasars, Seyferts, emission line galaxies).

Although obscured accretion seems to provide the most likely explanation for the optical and X–ray flux distribution of unconventional AGN, alternative possibilities are viable. At very faint optical fluxes (log \( \frac{f_X}{f_{opt}} > 1 \)) the observed properties would be consistent with both high redshift
the latter an handful of objects are reported by Maiolino et al. (1998). Whether Compton thick AGN are common at high redshift is still debated (Fabian et al. 2002) though the ultra-luminous infrared galaxy IRAS 09104+4109 is very similar. Conversely, the weak rest–frame optical–UV emission is shifted in the R band explaining the extremely faint optical magnitudes. As a consequence the optical to X–ray flux ratio changes in a non–linear way.

We have computed the optical magnitude in the R band and the 2–10 keV X–ray flux which would be observed for a source with the SED of Figure 2 from $z = 0$ to $z = 1.5$. The redshift tracks in the optical magnitude versus X–ray flux plane (Fig. 3) have been normalized to the observed X–ray flux and R magnitude of NGC 6240 and IRAS 09104+4109. The two objects are characterized by a similar SED but different X–ray luminosities (about $3 \times 10^{44}$ erg s$^{-1}$ and $10^{46}$ erg s$^{-1}$ respectively). The results clearly indicate that the observed high values of the X–ray to optical flux ratio are consistent with those expected by a population of high redshift, mildly Compton thick AGN with X–ray luminosities in the range $\log L_X = 44 - 46$ erg s$^{-1}$.

We have also tried to explain with a similar approach the distribution of $f_X/f_{opt}$ values of XBONG assuming that the underlying SED of the AGN powering the hard X–ray emission is that of a heavily Compton–thick object. The lower redshift track in figure 3, normalized to the locus of nearby objects in the BeppoSAX survey of Maiolino et al. (1998), is in relatively good agreement with the observed $f_X/f_{opt}$ and redshift distribution of the XBONG sample.

Although it seems reasonable to argue that a large fraction of unconventional AGN are obscured by Compton thick gas our approximations appear to be too much simple to draw quantitative conclusions. At the face value our model predicts that most of the sources with $\log f_X/f_{opt} > 1$ are mildly Compton thick AGN in the redshift range 0.5–1.5. The presence of a large population of Compton thick AGN at faint optical magnitudes has been put forward by Fabian et al. (2002). On the basis of a more sophisticated model they suggest that such a population would have redshifts ranging from 2 to 8 and could be detectable in Chandra deep fields.

The detection of strong FeKα features could in principle provide a powerful tool to check the space density and redshift distribution of Compton thick AGN. Although only an handful of objects exhibit obvious Kα lines (Bauer et al this volume) we expect to obtain more stringent constraints from an undergoing systematic spectral analysis of a carefully selected sample of unconventional AGN.

3. A toy model for unconventional AGN

In the following we try to further investigate the nature of unconventional AGN assuming that they are powered by heavily obscured accretion. In order to properly address this issue it is important to point out that as long as the absorption column density does not exceed values of the order of “a few” $10^{24}$ cm$^{-2}$ (mildly Compton–thick) the high energy spectrum recovers at $E > 10–20$ keV (see fig. 2); for higher values of the intrinsic absorption (heavily Compton–thick), Compton down–scattering strongly suppress the nuclear radiation at all energies and only reflected light with a quite flat slope can be seen (Matt et al. 1999). A strong iron line (EW $> 1$ keV) is expected in both the cases. At longer wavelengths the nuclear radiation is completely blocked by dust and the optical infrared spectrum is dominated by the host galaxy starlight. There are several examples of both mildly and heavily Compton thick sources in the local Universe discovered thanks to BeppoSAX. The prototype of the former is NGC 6240 at $z = 0.0245$ (Vignati et al. 1999) while for the latter an handful of objects are reported by Maiolino et al. (1998). Whether Compton thick AGN are common at high redshift is still debated (Fabian et al 2002) though the ultraluminous infrared quasars IRAS 09104+4109 at $z = 0.442$ (Franceschini et al. 2000, Iwasawa et al. 2001) and F15307 at $z = 0.92$ (Ogasaka et al. 1997) are good examples of mildly and heavily Compton thick AGN, respectively.
Fig. 3. The 2–10 keV flux versus the R band magnitude for a sample of unconventional AGN detected in the HELAS2XMM survey (empty squares) and in deeper Chandra and XMM–Newton surveys (filled squares). Green and cyan symbols refer to objects with $f_x/f_{opt}>1$ and XBONGs, respectively. The dash dotted lines represent the redshift tracks computed as described in the text. The filled symbols in the lower part of the diagram correspond to nearby heavily Compton thick AGN (Maiolino et al. 1998).
