We study slow light performance of molecular aggregates arranged in nanofilms by means of coherent population oscillations (CPO). The molecular cooperative behavior inside the aggregate enhances the delay of input signals in the GHz range in comparison with other CPO-based devices. Moreover, the problem of residual absorption present in CPO processes, is removed. We also propose an optical switch between different delays by exploiting the optical bistability of these aggregates.

PACS numbers: 42.65.-k 42.65.Pc 78.67.Sc

The optical engineering of the speed of light plays an important role in the development of all-optical devices for telecommunications. Among the different mechanisms exploited to obtain slow light,1,2 coherent population oscillations (CPO) deals with two-level systems and is feasible at room temperature3,4. It is worth mentioning that there is some controversy in this regard, since most of the experiments can also be explained by saturable absorption (SA)5,6. Being the source spectral width larger than the coherent hole of the absorption profile, some reasonable doubts raise about the existence of coherent population oscillations. From a theoretical point of view, a rate-equation analysis does not distinguish between both processes, and a density matrix formalism is required. To develop photonic applications, a large fractional delay (time delay normalized to the pulse length) is desirable in compact devices. Furthermore, bandwidths up to the GHz or THz-range and a constrained distortion of the input pulses are needed to integrate slow light mechanisms in nowadays communication networks. However, the delay decreases with the signal bandwidth, which makes difficult to achieve these objectives. Moreover, the residual absorption present in CPO processes leads to a greatly diminished output intensity when longer delays are sought. In this work we propose a new optical CPO-based device considering nanofilms of linear aggregates of dye molecules, so-called J-aggregates, which leads to a fractional delay up to 0.33 for 135-ps-long pulses while the ratio between the standard deviation of the output and input pulses reaches a value of 2.

More interestingly, the signal modulation is amplified instead of absorbed, which establishes a clear signature to distinguish between CPO and SA processes in typical two-level systems, since in the latter no gain in the weak intensity modulation can be achieved. We also show how the already predicted optical bistability on J-aggregates7 can provide an all-optical switch between two well differentiated time delays and pulse distortions. Remarkably J-aggregates display narrow absorption bands red-shifted with respect to those of the isolated molecules due to collective interaction, which leads to interesting optical phenomena studied in the last decades8. Because of disorder effects affecting these systems, only some of the molecules of the aggregate are coherently bound. In the most favorable situation, namely, at low temperatures, the number of molecules over which the excitation is localized is ~100, although a real aggregate is consisting of thousands of individual molecules. In view of these properties, we consider J-aggregates as modeled by an ensemble of inhomogeneously broadened two-level systems at low temperatures7,8. With regard to CPO processes, we study the response of an ultrathin film of oriented linear J-aggregates to a strong pump field E0 at frequency ω, and two sidebands E±1 at frequencies ω ± δ. Here δ is the beat frequency between fields. Due to disorder effects, the film can be considered as consisting of homogeneous aggregates of different coherent sizes N. By using the density-matrix formalism under the rotating wave and slowly varying amplitude in time approximations, we describe the state of a segment of size N as:

\[
\hat{\sigma}^N = (i(\omega - \omega_{ba}^N) - 1/T_2)\sigma^N - id^N EZ^N / \hbar \\
Z^N = 2id^N (\sigma^N E - \sigma^N E^*) / \hbar - (Z^N + 1)/T_1 
\] (1)

Here \(\sigma^N\) is the slowly varying in time coherence between the two levels which depends on the segment size N. The transition frequency and the dipole moment between the ground (a) and upper (b) energy levels of every segment read \(\omega_{ba}^N\) and \(d^N = d^2/\sqrt{N}\) respectively. The superscript 1 refers to single-molecule properties. We assume field polarization directed along the transition dipole moments of all the aggregates, which are parallel to each other as well as to the film plane. The relaxation time of the population inversion \(Z^N = (\rho_{bb}^N - \rho_{aa}^N)\) due to spontaneous emission is \(T_1 = T_1^N/N\), while \(T_2\) is related to other dephasing processes.

Field propagation in dense media can be described by means of an integral equation where the slowly varying approximation in time is considered but not in space. For film thickness smaller than the optical wavelength, spatially homogeneous polarization can be assumed, which leads to the following field equation,

\[
E = E^{in} + \frac{\mu_0 c L}{2} i\omega P ,
\] (2)
where $\mu_0$ is the permeability constant, $c$ is the speed of light and $L$ is the film thickness. The incident field is $E^{in}(t) = E_0 + E_1 \exp(-i\delta t) + E_{-1} \exp(i\delta t)$. The second term accounts for the field created by the molecules polarized by the incident field. We checked the full propagation integral to raise the same results as Eq. (2), for films of tens of nanometers, a thickness achievable by the spin coating technique \[10\]. Thus, for simplicity and to gain a deeper analytical insight, we will restrict ourselves to this case. Equation (2) resembles that found by Lu et al., who proved that local field effects can improve the slow light performance in a hybrid nanocrystal complex \[11\].

The polarization is calculated by considering the contributions of all coherent segments of different sizes, $P = N_0 \sum_N p(N) d^N \sigma^N$. Here $N_0$ is the density of localization segments and $p(N)$ refers to the disorder distribution function over localization lengths. Note that the size dispersion of the coherent segments in the system results from the inhomogeneous broadening affecting the J-band at low temperatures, which mainly gives rise to the fluctuation of transition energies $h\omega_{ba}^N$. As in Ref. \[1\], we replace the average over sizes by one performed over the normalized detunings $\Delta N = (\omega - \omega_{ba}^N)/T_2$. The distribution $p(N)$ indeed can be accessible by absorption experiments and is considered as Gaussian-like hereafter:

$$\sum_N p(N) \sim \int_{-\infty}^{\infty} \frac{\exp\left(-\frac{(\Delta N - \Delta_0)^2}{2\sigma^2}\right)}{\sqrt{2\pi\sigma^2}} d\Delta N,$$

(3)

$\Delta_0 = (\omega - \omega_0)T_2$ being the detuning between the incident frequency and the mean of the transition frequency distribution $\omega_0$. The magnitude of the J-band resulting from the inhomogeneous broadening is denoted by $G$ in units of $1/T_2$. From now on size dispersion effects are restricted to these detuning effects in our calculations, for the sake of simplicity. Thus, we will substitute the size-dependent quantities by its main value in the aggregate and remove the index $N$, i.e., $T_1 = T_1$ and $d^N = d$.

Similarly to Ref. \[12\], we treat Eqs. (1) to all orders in the strong field $E_0$, while keeping only first-order terms in the weak fields $E_{\pm 1}$. Within this approximation, the solutions to Eqs. (1) are found by considering the Floquet harmonic expansion: $\sigma^N = \sigma^N_0 + \sigma^N_1 \exp(-i\delta t) + \sigma^N_{-1} \exp(i\delta t)$ and $Z^N = Z^N_{dc} + Z^N_1 \exp(-i\delta t) + c.c. \[12\].

$$\sigma^N_1 = \frac{d T_2}{h(\xi + \Delta N + i)} (E_1 Z^N_{dc} + E_0 Z^N_1),$$

$$\sigma^N_{-1} = \frac{-d T_2}{h(\xi - \Delta N + i)} (E_0 Z^N_1 + E_{-1} Z^N_{dc}),$$

$$Z^N_1 = \frac{-2d T_2}{h(\xi + i r)} (E_0 \sigma^N_{-1} + E_1 \sigma^N_0) + \frac{2d T_2}{h(\xi + ir)} (E_0 \sigma^N_{1} + E_{-1} \sigma^N_0),$$

(4) where $\xi = \delta T_2$ and $r = T_2/T_1$. The DC response of the population is $Z_{dc}$, and $Z_1$ accounts for the coherent population oscillations, which leads to the absorption dip.

We will refer to the Rabi frequency defined in units of $1/T_2$ as $\Omega_{0,\pm 1} = 2d E_{0,\pm 1} T_2/h$ from now on as:

$$\Omega_{0,\pm 1} = \Omega_{0,\mp 1}^N + i \gamma_R \sum_N p(N) \sigma^N_{0,\pm 1}.$$

(5)

Here $\gamma_R = \mu_0 |d|^2 N_0 \omega_{LT} T_2/2h$ is the collective superradiant damping of an ensemble of two-level molecules.

Once we algebraically solve Eqs. (1) and taking into account Eqs. (5) it can be demonstrated that:

$$\frac{\Omega_0}{\Omega_0^N} = \left[1 + \gamma_R \sum_N p(N)(1 + i \Delta N)^{-1}\right]^{-1},$$

(6)

$$\frac{\Omega_1}{\Omega_1^N} = \left[1 + i \gamma_R \frac{\Omega_0^2 \Omega_{-1}^N (\xi + 2i)}{2 \Omega_1^N} \sum_N p(N) Z^N_{dc}\right] \times \left[1 - i \gamma_R (\xi + i r) \sum_N p(N) Z^N_1 (\xi - \Delta N + i) + i \gamma_R \frac{|\Omega_0|^2 \xi}{2} \sum_N p(N) Z^N_{dc}\right]^{-1},$$

(7)

$$\frac{\Omega_{-1}^N}{\Omega_{1}^{N+1}} = \left[1 + i \gamma_R \frac{\Omega_0^2 \Omega_{-1}^N (\xi + 2i)}{2 \Omega_1^N} \sum_N p(N) Z^N_{dc}\right] \times \left[1 - i \gamma_R (\xi + i r) \sum_N p(N) Z^N_1 (\xi + \Delta N + i) - i \gamma_R \frac{|\Omega_0|^2 \xi}{2} \sum_N p(N) Z^N_{dc}\right]^{-1},$$

(8)

where $D^N = (\xi + i r)(\xi + \Delta N + i)(\xi - \Delta N + i) - |\Omega_0|^2 (\xi + i)$. Equation (6) has one or three roots depending on the parameters. This leads to bistable solutions for the strong field $\Omega_0$ when $\gamma_R$ is larger than a threshold value \[7\].

We consider an incident field such that $\Omega_1 = \Omega_{-1}$, leading to a sinusoidally modulated intensity with frequency $\delta$. Thus, Eqs. (7) and (8) can be simplified and the resulting fields fulfill $\Omega_1 = \Omega_{-1}^N$. The transmittance $T$ and the dephasing $\phi$ induced by the film is calculated by the ratio between the output and the input signals:

$$\frac{\Omega_1 + \Omega_{-1}}{\Omega_1^N + \Omega_{-1}^N} = T e^{i \phi},$$

(9)

Thus, the fractional delay is defined as $F = \phi/2\pi$.

We first analyze the case in absence of size dispersion. We take the parameters of Pseudoisocyanine-Br (PIC-Br) as it is one of the most studied J-aggregates. Hence, we use $T_1 = 37$ ps (corresponding to a homogeneous aggregate of size $N = 100$) and $T_2 = 0.027$ T. This value is consistent with measurements at low temperatures \[12\] and allows direct comparison with previous CPO works \[14\]. The transition dipole moment is $d^1 = 12.1$ D and
the concentration of aggregates is \( N_0 \sim 10^{23} \text{ m}^{-3} \). These parameters give values for \( \gamma_R \) around 10 for film lengths of tens of nanometers. As in the usual CPO case, the maximum delay is obtained when the pump field reaches the saturation intensity, which depends on \( \gamma_R \). Hereafter, and for each case shown, we will restrict ourselves to this optimal intensity. These values correspond to a photon flux of \( \sim 1.4 \times 10^{11} \text{ photon/cm}^2 \) for a 100-ps-length pulse, and a surface density of monomers \( \sim 10^{13} \text{ cm}^{-2} \). This means that the typical number of absorption and re-emission cycles per aggregate is \( \sim 1 \), a much smaller value than those usually occurring in J-aggregates experiments [15], and that allows to ensure photostability of the samples. Moreover these intensities are low enough to neglect the blue-shifted one-to-two exciton transitions, which supports the use of a two-level model [7].

Figure 1 shows the fractional delay and transmittance, calculated with Eq. (9), as a function of the normal-

\( \gamma \)

which accounts for the collective interaction within the aggregate, gives rise to higher fractional delays reaching values of \( \sim 0.2 \) for \( \gamma_R \sim 8 \). Values of \( \gamma_R > 8 \) allows bistability to appear, which introduces a large signal distortion. Therefore, only cases up to \( \gamma_R = 10 \) are shown. Figure 1 (right panel) shows how the transmission increases with \( \gamma_R \) as well. It must be noted that the system presents gain (\( T > 1 \)) in the weak probe electric fields for modulation frequencies close to those revealing the maximum fractional delay. We explain this behaviour as a strong scattering process from the pump to the weak field due to the transient temporal grating generated in CPO. This is clearly relevant as CPO processes in other media usually present non-desirable residual absorption. Hence, in such cases it may be necessary to amplify the signal after propagation through the slow light medium, specially for long media or high ion-densities [16]. The presence of gain in these films could overcome this drawback of CPO-based slow light while is revealed as a clear difference with SA processes in typical two-level media.

More relevant to telecommunication applications is the performance of the system with input pulse signals. To analyze the fractional delay and distortion of the output pulses after passing through the ultrathin film we numerically integrate Eqs. [1] together with Eq. [2]. To validate the simulations, we first check the numerical integration with the results previously obtained. Figure 1 shows the perfect agreement with the analytical predictions for the case of a sinusoidal input signal. Figure 2 depicts the fractional delay \( (F) \) and distortion \( (D) \) as a function of the pulse temporal width (defined as FWHM). The distortion is defined as the ratio between the output and input-pulse standard deviations. Although the maximum fractional delay is accompanied by a large distortion, values up to \( F = 0.33 \) are obtained with distortion 2 for 135-ps-long pulses, which gives \( \sim 7.5 \text{-GHz} \)

\( \text{bandwidth} \). These results notably improve previous data obtained by CPO-based slow light in semiconductor materials at GHz-bandwidths [17]. As mentioned before, increasing values of \( \gamma_R \) lead to larger delays. However, the distortion generated when bistability occurs limits in practice the values of \( \gamma_R \) up to 8 for \( G = 0 \) (no size dispersion). Note in Fig. 2 (inset) how the transmittance of the electric field is larger than 1 for most of the analyzed input-pulse widths, in agreement with results of Fig. 1.

Let us now analyze the influence of the size dispersion on the slow light performance. To numerically integrate Eqs. [1] and [2] with the inclusion of the inhomogeneous broadening, we carefully choose the sampling under the curve defined by Eq. [3] to reproduce the analytical results for a sinusoidal signal. We now focus on the effects of size dispersion on pulse propagation. As it is well known, the presence of inhomogeneous broadening reduces the slow light performance, as can be seen in Fig. 3 where the fractional delay and distortion are plotted against the input-pulse width. A value of \( G = 3 \) already reduces the fractional delay up to 5 times with respect to the value obtained without size dispersion. However, as shown at right panels of Fig. 3 the detrimental effect of a larger inhomogeneous linewidth can be compensated...
by increasing the value of $\gamma_R$. Larger values of $\gamma_R$ can be obtained by modifying the temperature or increasing the aggregates concentration in the sample [7].

We finally propose a mechanism to take advantage of the optical bistability present in J-aggregates nanofilms for slow light applications. Bistability allows to rapidly change between two different output intensities for the same input. As the fractional delay depends on $|\Omega_0|^2$, this property turns out into a switch between two well-differentiated delays and distortions for the same $|\Omega_0|^2$. Fig. 3 depicts this process for a value of $\gamma_R = 10$ and no size dispersion, where the bistability loop can be found for $0.69 < (|\Omega_0|^2) < 0.76$. Starting in the lower branch of the loop (position (1) in Fig 4), and after propagating the first pulse, a short pulse in the input signal causes the system to switch to position (2), in the upper branch. Fractional delays achieved in positions (1) and (2), for a 111-ps-length pulse are 0.43 and 0.09 respectively, while the distortion values are 3.6 and 1.07. The lowest switching time is limited by $T_1$, according to simulations, being of some tens of ps for J-aggregates films.

In conclusion we showed that J-aggregates ultrathin films can produce large fractional delays by means of CPO processes, even in presence of inhomogeneous broadening and thanks to the cooperative behavior of the aggregate molecules. This system does not suffer from residual absorption in the weak probe fields, in opposition to the usual CPO-based slow light. We also demonstrated how optical bistability could be used to produce a fast switch between different delays. We believe these organic compounds present a viable alternative to semiconductor slow light devices in the nanoscale. To this end, our results can motivate further research at room temperature operation and telecommunication bands. In this sense, the development of new aggregates such as Porpho-cyanines [18] provides great opportunities. Moreover, new studies including processes such as one-to-two exciton transitions and exciton-exciton annihilation are currently in progress. These effects seem to counteract the killing action of the inhomogeneous broadening [19], which would impose better experimental conditions to obtain the delays shown in this work.
