A GLIMPSE OF THE CONFORMAL STRUCTURE OF RANDOM PLANAR MAPS

Nicolas Curien*

Abstract

We present a way to study the conformal structure of random planar maps. The main idea is to explore the map along an SLE (Schramm–Loewner evolution) process of parameter $\kappa = 6$ and to combine the locality property of the SLE$_6$ together with the spatial Markov property of the underlying lattice in order to get a non-trivial geometric information. We follow this path in the case of the conformal structure of random triangulations with a boundary.

Under a reasonable technical assumption that we have unfortunately not been able to verify, we prove that the limit of uniformized random planar triangulations has a fractal boundary measure of Hausdorff dimension $\frac{1}{3}$ almost surely. This agrees with the physics KPZ predictions and represents a first step towards a rigorous understanding of the links between random planar maps and the Gaussian free field (GFF). Several conjectures related to the SLE$_6$ and the GFF are presented at the end of the paper.

Figure 1: A random triangulation embedded not isometrically in $\mathbb{R}^3$ and an approximation of its uniformization on the two-dimensional sphere.

Keywords: Random planar maps, conformal geometry, SLE processes, quantum gravity.

Introduction

What does a typical random metric on the two-dimensional sphere look like? This concept plays a crucial role in the theory of two-dimensional quantum gravity where the famous KPZ relations (Knizhnik, Polyakov and Zamolodchikov [24]) are supposed to relate the dimensions of (some) sets under the random—or “quantum”—metric on the sphere $S^2$ to their dimensions with respect to the standard Euclidean metric. Nowadays, there are two mathematically rigorous approaches trying to make sense of “the random metric on $S^2$”.

Random planar triangulations. The first one is the theory of random planar triangulations (RPT) known as “dynamical triangulations” in theoretical physics [2]. The basic idea is to discretize a continuous surface into finitely many triangles (or in any other basic tile) glued together: a triangulation that approximates the space. It seems natural to expect that such a discretization of “the random metric on $S^2$” into $n$ triangles should yield a random triangulation $T_n$ uniformly distributed over the set of all triangulations of $S^2$ with $n$ faces.

Starting from this discrete model, Le Gall [29] (see also Miermont [35] for the quadrangular case) has shown that after renormalizing the distances in $T_n$ by $n^{-1/4}$, the resulting random compact metric space indeed converges in distribution (for the Gromov–Hausdorff topology) towards a random compact metric space called the Brownian map. This random metric space thus captures the metric properties of what a random metric on $S^2$ should be (in particular it is of Hausdorff dimension 4 [30]). However, although the Brownian map is known to be homeomorphic to the sphere (see [31, 36]) the embedding is not canonically defined and thus the Brownian map cannot yet unambiguously be seen as $S^2$ endowed with a random metric.

Gaussian free field. The second approach is based on the Gaussian free field (GFF) which is a conformally invariant random distribution $h$ on the sphere, see [42] for details. The “random metric on $S^2$” is then formally given by

$$e^{\varrho h(z)}dz^2,$$

where $dz^2$ is the infinitesimal metric element on $S^2$ and $\varrho \geq 0$ is a parameter. The last display would be easy to define if $h$ were a random smooth function, but unfortunately up to now, no rigorous construction is known to make sense of (1) (except in dimension 1, see [11]). Still, there are several (equivalent) ways to make sense of (1) in terms of a random measure (originally by Kahane in [22]) and certain forms of the KPZ relations have been proved in this setup, see [17, 38, 39].

Conformal structure of RPT

Though both paths have not succeeded in formally constructing a random metric living on $S^2$, we see that these approaches have different drawbacks: The RPT theory does yield a continuous metric but the embedding on the sphere is lacking, whereas in the GFF approach, the sphere (hence the embedding) is a built-in feature of the model but the random metric seems hard to construct. However, the two theories are believed to eventually converge. This conjectured link has been made particularly clear (but remains unproven) by Duplantier & Sheffield in [17] (see also [41]) and consists in understanding the conformal structure of random planar maps (triangulations in this work) and to relate it to the GFF. The goal of this work is to propose a possible way to rigorously begin this understanding.

Formally, we focus here on the model of the uniform infinite half-planar triangulation (UIHPT) which is an infinite random triangulation $T_{\infty,\infty}$ with an infinite simple boundary obtained by Angel
[3] as the local limit of triangulations with simple boundary whose size and perimeter both tend to infinity, see Section 1 for its definition and basics about planar maps. The UIHPT is also given with a distinguished oriented edge, called the root edge and oriented so that the infinite face is lying on its right, see Fig. 2. From many respects, this model of random planar map is the simplest of all. The key property of this random lattice is its particularly simple spatial Markov property which roughly says that after exploring a finite simply connected region of the map, then the remaining part is independent of the explored region and has the same law as the original lattice. See Section 1.2 for a precise statement. The spatial Markov property of random planar maps has been studied in details in [6] and was at the core of many non-trivial results, see [4, 5, 9, 33].

Our goal is to study the conformal structure of the boundary of the UIHPT. Formally, one consider $T_{\infty, \infty}$ as a random Riemann surface by simply seeing each triangle as an (Euclidean) equilateral triangle and gluing the charts along the edges and vertices of the map, see the work of Gill & Rohde [18] and Section 2.2 for details. Using the Riemann uniformization theorem, one can map the simply connected Riemann surface with a boundary obtained by the previous device onto the upper half plane $\mathbb{H} = \{z \in \mathbb{C} : \Re(z) > 0\}$. This mapping is unique provided that we fix the images of the origin and target of the root edge to be $-1/2$ and $1/2$ and send $\infty$ to $\infty$.

Figure 2: A part of a UIHPT and its uniformization (artistic drawing)

The conformal drawing of the UIHPT (that is the image of the edges of $T_{\infty, \infty}$ by the above mapping) will be denoted by $\mathcal{T}_{\infty, \infty}$ and we will commit an abuse of terminology when we will still speak about its vertices, edges and faces which are defined in an obvious way. For $k \geq 0$, the position of the $k$th vertex on the right of the origin of $\mathcal{T}_{\infty, \infty}$ is denoted by $X_k$, in particular $X_0 = -1/2$ and $X_1 = 1/2$. For $n \geq 1$, we consider the random probability measure $\mu_n$ on $[0,1]$ defined by

$$\mu_n = \frac{1}{n} \sum_{k=1}^{n} \delta_{X_k/X_n}.$$  

**Theorem** 1. From any sequence of integers tending to $+\infty$ one can extract a subsequence $n_k \to \infty$ such that $\mu_{n_k}$ converges as $k \to \infty$ in distribution towards a random probability measure $\mu$ such that almost surely

- $\mu$ is non-atomic,
- $\mu$ has topological support equal to $[0,1]$,
- the Hausdorff dimension\(^1\) of $\mu$ is $1/3$.

\(^1\)Recall that the dimension of a measure is the infimum of the dimensions of Borel sets of full mass
**The star condition.** We used the label Theorem* because our proof relies on a technical assumption denoted by (⋆) (see Section 2.5) that we strongly believe to hold, but have not been able to rigorously derive. Similarly, the results denoted by Proposition*, Corollary*, Lemma* etc... all rely on (⋆). See Section 5 for a discussion and supports for (⋆).

To our opinion, the value of this paper does not entirely lie in the statement of Theorem* 1 but rather on the strategy (that we believe is new) employed to study the conformal geometry of random planar maps. In particular, it might be the case that our work actually yields a characterization of the measure $\mu$ which could then be identified with the measure constructed from the exponential of the Gaussian free field in [17, Section 6] for the particular parameter $\varrho = \sqrt{8/3}$, see the last paragraph of this Introduction. We refer to Section 5 for a discussion and for the statements of several conjectures about links between the GFF, SLE and stable processes which we hope can directly be answered by specialists in the field.

**Strategy**

Our approach to investigate the conformal structure of random planar triangulations is based on their exploration by an independent $\text{SLE}_6$ process. Recall that for $\kappa \geq 0$, the $\text{SLE}_\kappa$ processes have been introduced by Schramm [40] in order to describe interfaces of conformally invariant models in two dimensions. See [27] for background. The $\text{SLE}_6$ process has a characteristic feature (that he shares with Brownian motion), which is called the locality property. The latter roughly means that its growth is locally defined and does not depend on the full curve, see Section 2.4. This property is one of the keys in the determination of the Brownian intersection exponents by Lawler, Schramm and Werner [28] and is also central in this work.

Formally, the exploration of the UIHPT by an $\text{SLE}_6$ is defined as the exploration of $\mathcal{T}_{\infty, \infty}$ by an independent chordal $\text{SLE}_6$ on $\mathbb{H}$ started from 0. *A priori*, the exploration of the UIHPT thus depends on its whole conformal structure since we formally need its uniformization $\mathcal{T}_{\infty, \infty}$ to define it. However, the locality property of $\text{SLE}_6$ will imply that this exploration can in fact be performed by discovering the UIHPT “step-by-step” revealing only the parts necessary for the $\text{SLE}_6$ to displace.

This will show that the $\text{SLE}_6$ exploration of the UIHPT is Markovian, in the sense that the submap discovered after some time (made of the triangles traversed by the $\text{SLE}$ as well as the finite regions they enclose) is independent of the remaining of the map which is distributed as a standard UIHPT, see Section 1.2. Using the explicit description of the spatial Markov property of the UIHPT also known as Angel’s peeling process (see [4, 5] and Section 1.2), we are able to understand the algebraic variations of the boundary length seen from $\pm \infty$ in the unexplored map. More precisely when the $\text{SLE}$ is located on a boundary edge of the explored region, we can define two integer numbers $\mathcal{H}^+$ and $\mathcal{H}^-$ representing the variations of the boundary lengths towards $\pm \infty$ from this edge compared to the original boundary lengths from the root edge of the map, see Fig. 3.

In Theorem* 2 we show, under the key technical assumption (⋆), that this horodistance process $(\mathcal{H}^+(i), \mathcal{H}^-(i))_{i \geq 0}$ is mainly driven by the spatial Markov property of the map and converges (in distribution in the Skorokhod sense) after normalization by $n^{2/3}$ towards a multiple of pair $(S^+, S^-)$ made of independent standard $\frac{3}{2}$-stable spectrally negative Lévy processes, more precisely

$$\left(\frac{\mathcal{H}^+([nt])}{n^{2/3}}, \frac{\mathcal{H}^-([nt])}{n^{2/3}}\right) \xrightarrow{(d)} \frac{n}{n \to \infty} -3^{-2/3} \cdot (S^+_t, S^-_t)_{t \geq 0}. \quad (2)$$

The basic idea of the proof of Theorem* 1 is to connect these horodistance processes to a geometric property, namely the fact that the $\text{SLE}_6$ bounces off $\mathbb{R}_+$ and $\mathbb{R}_-$, [44]. On an intuitive level at least, the times when $\mathcal{H}^-$ (resp. $\mathcal{H}^+$) reaches a new minimum corresponds to a visit of $\mathbb{R}_-$ (resp. $\mathbb{R}_+$) by
the SLE$_6$ process, see Section 3. We then compute, in two ways, the number $C(\varepsilon, n)$ of times the SLE$_6$ exploration of $\mathcal{T}_{\infty, \infty}$ is alternatively bouncing of $\mathbb{R}_+$ and $\mathbb{R}_-$ between the point $X_{[\varepsilon n]}$ and $X_n$. On the one hand, using the scaling limit of the horodistance process (2) one is capable to compute $C(\varepsilon, n)$ (to be precise, its limit) in terms of interlaced minimal records of $S^+$ and $S^−$ (see Corollary 11) and we find that as $n \to \infty$

$$C(\varepsilon, n) \approx \frac{3\sqrt{3}}{2\pi} \frac{1}{\log \varepsilon}.$$  

(3)

On the other hand, conditionally on $\mathcal{T}_{\infty, \infty}$ (and a fortiori on $(X_k)_{k \geq 0}$) it is know by the work of Hongler and Smirnov [20] (see also Corollary 14 below) that the number of alternative commutings to $\mathbb{R}_+$ and $\mathbb{R}_-$ an SLE$_6$ is doing after having swallowed the point $X_{[\varepsilon n]}$ until it swallows the point $X_n$ is roughly of order

$$C(\varepsilon, n) \approx \frac{\sqrt{3}}{2\pi} \log \frac{X_n}{X_{[\varepsilon n]}}.$$  

(4)

Equalizing (3) and (4) we find that $X_{[\varepsilon n]} / X_n \approx \varepsilon^{3/2}$. In terms of the limiting random measure $\mu$ this will imply that $\mu[0, \varepsilon^3] \approx \varepsilon$ or equivalently $\mu[0, \varepsilon] \approx \varepsilon^{1/3}$. Generalizing and sharpening this result when the point 0 is replaced by a typical point of $\mu$ is at the core of the proof of Theorem* 1 (iii).

We conclude this introduction by pointing the conjectured link of our work with the Gaussian free field and the KPZ relations (at least in the case of “pure gravity”). The interested reader should consult [17, 41] for details, references and additional open questions.

Back to KPZ

As explained above, the conformal structure of random planar maps (in this work, the UIHPT) is believed to be closely related to the exponential of the Gaussian free field (GFF). More precisely, if $h$ is an instance of the mean zero GFF on $\mathbb{H}$ with zero boundary condition (see [41, Section 3]) then we can define a random measure $\mu_\varphi$ on $\mathbb{R}$ formally obtained as

$$e^{\varphi h(z)/2}dz,$$

where $dz$ is the Lebesgue measure on $\mathbb{R}$. Since we (formally) have $E[h(x)h(y)] = -2\log |x - y|$, the measure $\mu_\varphi$ can be constructed using Kahane’s theory of Gaussian multiplicative chaos, see
where $\mu_\varrho$ is called the log-normal multi-fractal random measure. An alternative equivalent construction of this measure using circle average regularization can be found in [17, Section 6]. We refer the reader to the review [39, Section 5] for details of these constructions. For the particular parameter $\varrho = \sqrt{8/3}$ this measure is conjectured to describe the limit of the discrete counting measure on the boundary of a conformally uniformized map similar as the one considered in this work. More precisely, it is conjectured (see [17, 41]) that:

**Question 1.** The random measures $\mu_n$ converge in distribution towards the random probability measure

$$\tilde{\mu}_{\varrho} = \frac{\mu_{\varrho}(\cdot \cap [0,1])}{\mu_{\varrho}[0,1]} \quad \text{with} \quad \varrho = \sqrt{8/3}.$$ 

Duplantier & Sheffield [17] and Rhodes & Vargas [38] recently showed that the KPZ relations [24] derive from the analysis of the multi-fractal spectrum of the random measure $\mu_\varrho$. This analysis has been undertaken first in [8] where it is shown that the dimension of $\mu_\varrho$ is $1/3$ when $\varrho = \sqrt{8/3}$ (see also the proof of Theorem 6.1 in [17] for a different approach). Hence Theorem* 1 strongly supports Question 1 and can be seen as the first step towards the understanding of the full multi-fractal spectrum of $\mu$ and thus of the KPZ relations.

The paper is organized as follows. In the first section we recall the necessary background on the UIHPT including its construction and the crucial spatial Markov property. The notion of Markovian exploration is introduced as well as basics on the $\frac{3}{2}$-stable process. The second section is devoted to the $\text{SLE}_{\frac{3}{2}}$ exploration of the UIHPT. We explain there why the locality property of the SLE resonates with the spatial Markov property of the underlying lattice and implies under assumption (*) the convergence (2). In Section 3, we show how to translate (2) into geometric information by studying the alternative bouncings of the SLE and interlaced minimal records of two independent stable processes. The proof of Theorem* 1 can be found in Section 4. Unsurprisingly, the last section contains conjectures, comments and possible extensions for future works.

**Acknowledgments:** We are indebted to Jean Bertoin and Jean-François Le Gall for crucial advices on how to prove Proposition 8 and 12 respectively. Thanks also go to Wendelin Werner for a stimulating discussion and to Vincent Vargas for helpful comments on a first version of this work. We are grateful to the organizers of the conference “Planar statistical physics (2012)” in les Diablerets where this work started during a transit on the everlasting ski-lift “Perche-Conche”.
1 Background on the half-plane UIPT

1.1 The UIHPT

Recall that a planar map is a finite connected planar graph embedded in the sphere $S_2$ seen up to continuous deformations that preserve the orientation. There is a natural notion of vertex, edge and face in a planar map. The degree of a face is the number of half-edges surrounding the face. As usual, all the maps considered in this work are rooted, that is, given with a distinguished oriented edge $\vec{e}$ called the root of the map. A triangulation is a map whose faces are all of degree 3. Except explicitly mentioned we will focus on type-II triangulations, that are triangulations without loops but possibly multiple edges.

A triangulation with a simple boundary is a planar map whose faces are all triangles except possibly the face on the right-hand side of the root edge called the external face which is bounded by a non-intersecting cycle (no pinch-points). In this work we only deal with simple boundaries and thus sometimes drop the adjective simple to lighten the writing. The perimeter of a triangulation with boundary is the degree of the external face, and a triangulation with a boundary of perimeter $p$ is also called a triangulation of the $p$-gon. The size of a triangulation with a boundary is its number

of inner vertices (i.e. not located on the boundary). By convention, the only triangulation of the 2-gon of size 0 is made of a single oriented edge.

\begin{figure}
\centering
\includegraphics[width=\textwidth]{figure}
\caption{A triangulation of the 12-gon of size 7.}
\end{figure}

Local limits. Following [7, 10] we recall the local topology on the set of planar maps. If \( m, m' \) are two rooted maps, the local distance between \( m \) and \( m' \) is

\[ d_{\text{loc}}(m, m') = \left( 1 + \sup\{ r \geq 0 : B_r(m) = B_r(m') \} \right)^{-1}, \]

where \( B_r(m) \) denotes the map formed by the vertices and edges of \( m \) which are at graph distance smaller than or equal to \( r \) from the origin of the root edge in \( m \). The set of all finite rooted triangulations with boundary is not complete for this metric and we shall work in its completion formed by adding infinite maps (see [14] for a detailed exposition in the quadrangular case). For any \( p \geq 2 \), we denote by \( T_{n,p} \) a random variable uniformly distributed on the set \( T_{n,p} \) of all triangulations (of type II) of the \( p \)-gon having size \( n \). The Uniform Infinite Half-Planar Triangulation (UIHPT) is obtained as a local limit of uniform triangulations with boundary by first letting their sizes tend to infinity and next sending their perimeters to infinity. More precisely, Angel & Schramm [7] and Angel [3] proved the following convergences in distribution for \( d_{\text{loc}} \)

\[ T_{n,p} \xrightarrow{d} T_{\infty, p} \xrightarrow{p} T_{\infty, \infty}, \]

where \( T_{\infty, p} \) is a random rooted infinite triangulation of the \( p \)-gon called the UIPT (for Uniform Infinite Planar Triangulation) of the \( p \)-gon and \( T_{\infty, \infty} \) is the UIPT of the half-plane denoted by UIHPT (see [15] for similar statements in the quadrangular case). This is the main character of this paper.

The root edge of \( T_{\infty, \infty} \) will always be denoted by \( \vec{e} \) (the external face is on its right) or \( e \) if we consider the unoriented edge. The infinite simple boundary of \( T_{\infty, \infty} \) can be identified with \( \mathbb{Z} \) by declaring that the root edge is \( 0 \rightarrow 1 \). The UIHPT enjoys an invariance under re-rooting: for any \( k \in \mathbb{Z} \) the planar map obtained from \( T_{\infty, \infty} \) by re-rooting at the edge \( k \rightarrow k+1 \) is still distributed as the UIHPT. For this reason we might be loose on the precise location of the root edge in what follows.

1.2 One-step peeling of the UIHPT

One of the very nice features of the UIHPT is its spatial Markov property that can roughly be described as follows: Assume that we explore a simply connected region \( R \) of \( T_{\infty, \infty} \) that contains
the root edge, then the exterior of $\mathcal{R}$ is independent of $\mathcal{R}$ and is distributed as UIHPT. In order to make this statement precise we shall need some background. See [5] for more details.

**Enumeration.** We gather here several results about (asymptotic) enumeration of planar triangulations, see [3, 4] and the references therein for their derivations. For $n \geq 0$ and $p \geq 2$ we have the following asymptotic equivalent for $\# T_{n,p}$:

$$\# T_{n,p} \xrightarrow{n \to \infty} C_p \left( \frac{27}{2} \right)^n n^{-5/2}. \quad (5)$$

The exponent $5/2$ is typical of enumeration of planar maps and plays a crucial role. Thanks to this, the series $\sum_{n \geq 0} \# T_{n,p} (2/27)^n$ is finite and we denote its sum by $Z_p < \infty$. In fact, the numbers $Z_p$ can be exactly computed

$$Z_p = \frac{(2p-4)!}{(p-2)!p!} \left( \frac{9}{4} \right)^{p-1} \quad \text{for } p \geq 2. \quad (6)$$

**Definition 1.** The free Boltzmann distribution of the $p$-gon is the probability measure on $\cup_{n \geq 0} T_{n,p}$ that assigns a weight $(2/27)^n Z_p^{-1}$ to each triangulation of the $p$-gon of size $n$.

**One-step peeling.** We now present the version of the spatial Markov property that we will use. This describes the conditional laws of the different maps we obtain from $T_{\infty,\infty}$ after conditioning on the face that contains the root edge $e$. See [3] for the proofs.

Let $T_{\infty,\infty}$ be a UIHPT. Assume that we reveal the face on the left of the root edge $\vec{e}$, this operation is called the one-step peeling transition. Three (or two by symmetry) situations may appear depending on the “form” of the triangle revealed. Let us make a list of the possibilities and describe the probabilities and the conditional laws for each case. The set of forms is

$$\text{Forms} := (C,1) \cup \bigcup_{k \geq 1} \{(G,-k), (D,-k)\}.$$ 

To help the reader remind the notation remember that “C” stands for center, “G” for gauche (left in French) and “D” for droite (right in French). Here are all the possible cases:

- The revealed triangle could simply be a triangle with a vertex lying in the interior of $T_{\infty,\infty}$ (i.e. not on the boundary), see Fig. 5. We say that the revealed triangle is of form $(C,1)$. This event happens with probability $q_1$ where

$$q_1 = \frac{2}{3}.$$ 

The remaining triangulation (in gray in Fig. 5) denoted by $\text{Peel}(T_{\infty,\infty}; e)$ is formed after removing the revealed triangle from $T_{\infty,\infty}$ and rooting the resulting map at the edge of the revealed triangle which is incident to the initial root vertex. Conditionally on the form of the revealed triangle being $(C,1)$ then $\text{Peel}(T_{\infty,\infty}; e)$ has the same distribution as $T_{\infty,\infty}$.
• Otherwise, the revealed triangle has its three vertices lying on the boundary of $T_{\infty,\infty}$ and the third one is either $k \geq 1$ edges on the left of the root edge, in which case the triangle is said to be of form $(G, -k)$ or $k$ edges on the right of the root edge in which case the triangle is said to be of form $(D, -k)$, see Fig. 6. Note that $k > 0$ because loops are not allowed since we are working with 2-connected triangulations. By symmetry, these two events have the same probability $q_{-k}$ where

$$q_{-k} = \frac{(2k - 2)!}{4k(k - 1)!(k + 1)!}.$$

The revealed triangle thus encloses a triangulation with simple boundary of perimeter $k+1$ (the part in dark gray on Fig. 6). Since $T_{\infty,\infty}$ has only one end, this enclosed part must be finite. The remaining infinite triangulation $\text{Peel}(T_{\infty,\infty}; e)$ is formed by removing the revealed triangle and the enclosed triangulation from $T_{\infty,\infty}$ and rooting the resulting infinite triangulation with infinite boundary at the only edge adjacent to the revealed triangle.

Then, conditionally on the fact that the revealed triangle has its third vertex lying $k$ edges away from the root edge, the enclosed triangulation and $\text{Peel}(T_{\infty,\infty}; e)$ are independent, the first one follows a Boltzmann of the $k+1$-gon (see Definition 1) and $\text{Peel}(T_{\infty,\infty}; e)$ is a UIHPT.

**Remark 1.** Notice that conditionally on $k = 1$, the enclosed triangulation can be of size 0 with probability $Z_2^{-1} = 8/9$ (see (6)) in which case the revealed triangle is like “glued” on the boundary, see Fig. 7 below.
See Fig. 7. In the rest of the paper, we denote by $F$ a random variable over Forms which has the law of the form of a one-step peeling of the UIHPT, that is

$$P(F = (C, 1)) = q_1, \quad \text{and} \quad P(F = (G, -k)) = P(F = (D, -k)) = q_{-k} \quad \text{for } k \geq 1. \quad (7)$$

![Figure 7: The exposed edges are in fat black lines and the swallowed ones are in fat gray lines. One the right, the two cases when the form is $(D, -1)$ and $(G, -1)$ and the enclosed triangulations are of size 0.](image)

### 1.3 Markovian exploration

Let $T$ be an infinite triangulation with an infinite simple boundary such that $T$ has only one end. Extending what we have done in the case of the one-step peeling of $T_{\infty, \infty}$, for any non-oriented edge $a$ on the boundary of $T$ we denote by $\text{Peel}(T; a)$ the triangulation obtained from $T$ by removing the triangle adjacent to $a$ as well as the finite region it may enclose, rooted as in the preceding section. Similarly, define the form of the revealed triangle as before. We call this operation peeling the edge $a$ in $T$.

An exploration of $T_{\infty, \infty}$ is a sequence of nested subtriangulations\(^2\) of $T_{\infty, \infty}$

$$\cdots \subset T_n \subset \cdots \subset T_2 \subset T_1 \subset T_0 = T_{\infty, \infty}$$

such that for any $i \geq 0$ the triangulation $T_{i+1}$ is obtained from $T_i$ by the peeling of an edge $a_i$ on the boundary of $T_i$. For each $i \geq 0$, we denote by $K_i$ the “complement” triangulation of $T_i$ in $T_{\infty, \infty}$ made of all the triangles peeled at time $i$ as well as the finite regions they enclose. For definiteness, $K_0$ is the empty set. Alternatively, $K_i$ is obtained by cutting in $T_{\infty, \infty}$ along the boundary of $T_i$. This object is necessarily made of finitely many disjoint finite triangulations with simple boundary and will be called the “known, explored or discovered” part at time $i$ as opposed to $T_i$ which is the “unknown, unexplored or undiscovered” part.

In this work, we further assume that $a_0$ is the root edge and that for $i \geq 0$ the edge $a_i$ to be peeled at time $i \geq 1$ is located on the boundary of $K_i$ so that $(K_i)_{i \geq 0}$ is a sequence of growing triangulations with simple boundary (there is a single growing component).

Here comes the central notion:

**Definition 2** (Markovian exploration). An exploration process is Markovian if for every $i \geq 0$ the edge $a_i$ to peel at time $i$ is chosen using a (possibly random) algorithm that can use the knowledge of $K_i$ but does not depend on the unknown part $T_i$.

The main property of a Markovian exploration of the UIHPT is that the peeling steps are iid.

\(^2\)When we say a sequence of nested subtriangulations, we imagine that they are already given by nested embeddings. Indeed, in the case of presence of symmetries there could be many ways to see $T_1$ as a subtriangulation of $T_0$ etc... We do not intend to give a formal meaning to this and count on the intuition of the reader.
Proposition 1. During a Markovian exploration of $T_{\infty,\infty}$ we have:
- For each $i \geq 0$, $T_i$ is independent of $K_i$ and has the law of the UIHPT,
- The forms $(F_i)_{i \geq 0}$ of the triangles revealed during the exploration are i.i.d. copies of $F$.

Proof. The proof is done by induction. Imagine that at step $i \geq 0$, the triangulation $T_i$ to be explored is a UIHPT independent of the explored part $K_i$. Since the edge $a_i$ to be peeled is chosen independently of $T_i$, by the re-rooting property of the UIHPT (see Section 1.1) we deduce that the triangulation $T_i$ re-rooted at $a_i$ still has the law of the UIPT of the half-plane. We then trigger a one-step peeling transition and reveal the face adjacent to $a_i$ as well as the finite region it encloses. By the last section, the form $F_i$ of this face is independent of $K_i$ and has the same distribution as $F$, besides $T_{i+1} = \text{Peel}(T_i; a_i)$ is independent of $K_{i+1}$ and has the law of the UIHPT. 

1.4 Horodistances

Let $E$ be an exploration process of the UIHPT. We will now keep track of the position of the peeling position with respect to $-\infty$ and $+\infty$ by using “horodistances”. We use the notation introduced in the last sections where the dependence in $E$ is implicit.

Definition. Imagine that at step $i \geq 0$ we have discovered a subtriangulation $K_i \subset T_{\infty,\infty}$ and that the next edge to peel is $\vec{a}_i$ oriented such that the external face of $T_i$ is on its right. We define two integer numbers $H^-(i)$ and $H^+(i)$ which represent the algebraic variations of the distances seen from $-\infty$ and $+\infty$ of the edge $\vec{a}_i$ along the boundary. The definition should be clear on Fig. 8.

Formally, denote $\vec{a}^{-}_i$ the origin of $\vec{a}_i$ and $\vec{e}^-$ the origin of the root edge in $T_{\infty,\infty}$. Next consider the path $\gamma$ going from $\vec{e}^-$ towards $-\infty$ along the boundary of $T_{\infty,\infty}$ and $\gamma'$ the path going from $\vec{a}^-_i$ towards $-\infty$ along the boundary of $T_i$. Since $K_i$ is finite, these two paths eventually merge and $\gamma \setminus (\gamma \cap \gamma')$ as well as $\gamma' \setminus (\gamma \cap \gamma')$ are both finite. We define $H^-(i)$ as the algebraic difference of the lengths of $\gamma'$ and $\gamma$ that is

$$H^-(i) = |\gamma' \setminus (\gamma \cap \gamma')| - |\gamma \setminus (\gamma \cap \gamma')|.$$ 

The quantity $H^+(i)$ is defined similarly using the other endpoints of $a_i$ and $e$.

Splitting the variation. One might think that during an exploration process of $T_{\infty,\infty}$ the horodistances from $\pm\infty$ are only ruled by the peeling forms $(F_i)_{i \geq 0}$ of the exploration. This is not true since after peeling the edge $a_i$, the next edge $a_{i+1}$ to peel can be located anywhere on the
boundary of $K_{i+1}$ and could thus introduce a change in the horodistances. For convenience, we will thus consider intermediate half-integer steps in the horodistance processes $H^\pm$ which take into account only the variation of the horodistances due to the peeling steps.

Specifically, we introduce the following functions of forms: for every $f \in \text{Forms}$

$$\Delta^-(f) = \frac{1}{2} \cdot 1_{f=(C,1)} - \sum_{k \geq 1} k \cdot 1_{f=(G,-k)},$$

$$\Delta^+(f) = \frac{1}{2} \cdot 1_{f=(C,1)} - \sum_{k \geq 1} k \cdot 1_{f=(D,-k)}.$$  (8)

One can clearly recover $f$ using the pair $(\Delta^-(f), \Delta^+(f))$. Then for every $i \geq 0$ we set

$$H^\pm \left(i + \frac{1}{2}\right) = H^\pm(i) + \Delta^\pm(F_i).$$

In particular, when the exploration is Markovian then $H^\pm(i + \frac{1}{2}) - H^\pm(i)$ are i.i.d. of law $\Delta^\pm(F)$. Geometrically if $F_i \neq (C,1)$ then $H^\pm(i + \frac{1}{2})$ corresponds to horodistances of the only edge of the revealed triangle in $T_{i+1}$, thus $H^\pm(i + 1)$ would be equal to $H^\pm(i + \frac{1}{2})$ if the next edge to peel would be that one. However, when $F_i = (C,1)$ the quantities $H^\pm(i + \frac{1}{2})$ do not represent actual horodistances (since they are half-integers) but an “imaginary horodistance” of an edge sitting in between of the two edges of the revealed triangle in $T_{i+1}$. The quantity

$$\eta^\pm(i) := H^\pm(i + 1) - H^\pm \left(i + \frac{1}{2}\right)$$

thus corresponds to the difference of the new edge with respect to the “predicted” next edge to peel and heavily depends on the algorithm chosen for the exploration. Notice however that we always have

$$\eta^+(i) + \eta^-(i) = 0, \quad \text{for every } i \geq 0.$$  (10)

**Minimum process.** Finally, we will use an important geometric quantity that can be read from the horodistance process. Recall that in this work, we always peel on the boundary of the explored part so that $(K_i)$ is a growing triangulation with simple boundary. For any $i \geq 0$ we introduce the infimum process of the horodistance along half-integer times:

$$H^+(i) = \inf \left\{ H^+ \left(j + \frac{1}{2}\right) : j \leq i \right\} \land 0 \quad \text{and} \quad H^-(i) = \inf \left\{ H^- \left(j + \frac{1}{2}\right) : j \leq i \right\} \land 0.$$  (11)

It is easy to see by induction that $-H^+(i)$ (resp. $-H^-(i)$) can be interpreted as the number of edges of $T_{i,i}$ on the right (resp. left) of the root edge $\vec{e}$ that have been swallowed in $K_i$ so far, see Fig. 9. In particular, at time $i \geq 0$ the exploration process discovers a new triangle of form $(D, \cdot)$ and such that the third vertex of this triangle is lying on the original boundary of $T_{i,i}$ if and only if we have

$$H^+ \left(i + \frac{1}{2}\right) = H^+(i),$$

and similarly for the left-hand side with “+” replaced by “−”.
\[ \mathcal{H}^{-}(i) = -4 \quad \mathcal{H}^{+}(i) = -2 \]

**Figure 9:** The running infimums (along half-integer times) of the horodistance processes have a geometrical meaning. A new minimum of \( \mathcal{H}^{+} \) corresponds to a visit of the right boundary by the exploration process.

### 1.5 The spectrally negative \( \frac{3}{2} \)-stable process

Using the exact expression of the probabilities \((q_k)\) defined in Section 1.2, one gets that the random variables \( \Delta^{\pm}(F) \) defined by (8) and (9) are bounded above by \( 1/2 \) and satisfy

\[
E[\Delta^{\pm}(F)] = 0 \quad \text{and} \quad P(\Delta^{\pm}(F) = -n) \sim \frac{n^{-5/2}}{4\sqrt{\pi}}. \tag{12}
\]

In other words, \( \Delta^{+}(F) \) and \( \Delta^{-}(F) \) are both in the domain of attraction of the totally asymmetric stable random variable of parameter \( \frac{3}{2} \). Let us recall some basic facts about the standard \( \frac{3}{2} \)-stable spectrally negative Lévy process (with no positive jumps) with no drift which will be denoted by \((S_t : t \geq 0)\) in the rest of this paper. We refer to [12] for details. By standard we mean that the process \( S \) satisfies \( E[\exp(\lambda S_t)] = \exp(t\lambda^{3/2}) \) for all \( \lambda > 0 \) or equivalently its Lévy measure is given by

\[
\Pi(dx) = \frac{3}{4\sqrt{\pi}}|x|^{-5/2}dx1_{x<0}.
\]

This process enjoys the scaling property with parameter \( 3/2 \) that is \((S_t : t \geq 0) = (\lambda^{-2/3}S_{\lambda t} : t \geq 0)\) in distribution for any \( \lambda > 0 \).

**Figure 10:** Two (approximated) samples of the process \( S \).

The process \( S \) will appear in this work as the scaling limit of discrete walks. Recall that if \( \xi \) is a centered probability distribution over \( \mathbb{R} \) with increments bounded from above and such that
\[ P(\xi \leq -k) \sim ck^{-3/2} \text{ as } k \to \infty, \text{ if } X_1, \ldots, X_n, \ldots \text{ are i.i.d. copies of } \xi \text{ and if } Y_n = X_1 + \cdots + X_n \text{ is the cumulative sum then we have the following convergence in distribution in the sense of Skorokhod} \]
\[
\left( \frac{Y_{[nt]}}{(Kn)^{2/3}} \right)_{t \geq 0} \xrightarrow{(d) \over n \to \infty} (S_t)_{t \geq 0},
\]
with \( K = 2e\sqrt{\pi} \) and where \([x]\) denotes the largest integer less than or equal to \( x \), see [21].

In the rest of the paper, we write \( \frac{3}{2} \)-stable process for “standard spectrally positive \( \frac{3}{2} \)-stable process with no drift”.

**Proposition 2.** If \((F_i)_{i \geq 0}\) are i.i.d. random variables distributed as \( F \) then we have the following convergence in the sense of Skorokhod
\[
n^{-2/3} \left( \sum_{i=0}^{[nt]} \Delta^+(F_i), \sum_{i=0}^{[nt]} \Delta^-(F_i) \right)_{t \geq 0} \xrightarrow{(d) \over n \to \infty} 3^{-2/3} \cdot (S^+_t, S^-_t)_{t \geq 0},
\]
where \( S^+ \) and \( S^- \) are independent standard \( \frac{3}{2} \)-stable processes with no positive jumps.

**Proof.** Although the variables \( \Delta^+(F_i) \) and \( \Delta^-(F_i) \) are not exactly independent, this is more or less an easy consequence of (13). Let us provide the details. To gain independence we Poissonize time. More precisely, we give us a Poisson clock of parameter 1 and at each time \((s_i, i \geq 1)\) the clock rings, we sample a form \( F_i \) according to \( F \). Equivalently, every form \( f \in \text{Forms} \) appears with an independent Poisson clock of parameter \( P(F = f) \). For \( t \geq 0 \) let
\[
G_t = \sum_{F_i=\{G,j\}} j \quad \text{and} \quad D_t = \sum_{F_i=\{D,j\}} j
\]
respectively be the sums of the (negative) jumps of left and right forms. We also put \( C_t \) for the number of centered forms \((C,1)\) appeared before time \( t \) (which is thus a Poisson variable of parameter \( 2t/3 \)). Then we have
\[
\left( \sum_{s_i \leq t} \Delta^-(F_i), \sum_{s_i \leq t} \Delta^+(F_i) \right)_{t \geq 0} = (G_t, D_t)_{t \geq 0} + \frac{1}{2}(C_t, C_t)_{t \geq 0}.
\]
On the one hand, by Donsker’s theorem, we have
\[
\left( \frac{C_{nt} - \frac{2}{3}nt}{\sqrt{nt}} \right)_{t \geq 0} \xrightarrow{(d) \over n \to \infty} (B_t)_{t \geq 0},
\]
where \( B \) is a (multiple of a) Brownian motion. On the other hand, since \( G_t \) and \( D_t \) are now independent, by (12) and the fact that \( \sum_{k \geq 1} kq^{-k} = 1/3 \) we have
\[
\left( \frac{G_{nt} + \frac{nt}{3}}{n^{2/3}}, \frac{D_{nt} + \frac{nt}{3}}{n^{2/3}} \right)_{t \geq 0} \xrightarrow{(d) \over n \to \infty} 3^{-2/3} \cdot (S^-_t, S^+_t)_{t \geq 0},
\]
in distribution for the Skorokhod topology where \( S^- \) and \( S^+ \) are independent standard \( \frac{3}{2} \)-stable processes with no positive jumps. Remark now that the last display holds if we replace \( \frac{nt}{3} \) by \( C_{nt}/2 \) since the \( \sqrt{n} \) fluctuations of \( C_{nt} \) around \( 2n/3 \) are crushed by the above \( n^{2/3} \) renormalization. Using (14) and a standard depoissonization argument, this implies the proposition. \( \square \)
2 SLE$_6$ on the half-plane UIPT

The goal of this section is to explain how to discover a half-plane UIPT using an SLE$_6$ process and to prove that, under hypothesis (*), this exploration is the continuous limit of the discrete critical percolation interface in an appropriate sense. To help the reader digest our argument, we first recall the results of Angel [3, 4] on site percolation interface in $T_{\infty, \infty}$ using our formalism. We refer to [5] for more details.

2.1 Percolation exploration

Let $T_{\infty, \infty}$ be the half-plane UIPT. Conditionally on $T_{\infty, \infty}$ we color each vertex of the triangulation independently white or black with equal probability, except for the vertices of the boundary: color in white those on the right of the root edge and in black those on the left. See Fig. 11 below.

![Figure 11: Site percolation exploration on the UIHPT.](image)

It is possible to use the spatial Markov property of the UIHPT in order to discover step-by-step the percolation interface: at each step we reveal the triangle of the current boundary that lies between the black and the white component. If this triangle discovers a new vertex then reveal its color as well. It is easy to see that if this algorithm has been used since the beginning, then at each step there is a unique edge $\bullet - \circ$ located on the current boundary, see Fig. 11 above. This defines a Markovian exploration of the UIHPT, see [3, 4, 5]. If we denote by $H^\text{\textit{Perc}}^-(n)$ and $H^\text{\textit{Perc}}^+(n)$ the horodistances of the edge $a_n$ at the $n$th step of peeling then we have

**Theorem 3** (Angel [3]). We have the following convergence in distribution

$$
\left( \frac{H^\text{\textit{Perc}}^-([nt])}{n^{2/3}}, \frac{H^\text{\textit{Perc}}^+([nt])}{n^{2/3}} \right) \xrightarrow{d} 3^{-2/3} \cdot (S^-_t, S^+_t)_{t \geq 0}
$$

where $S^-$ and $S^+$ are independent standard $\frac{3}{2}$-stable processes with no positive jumps.

**Proof (Sketch).** For every $i \geq 0$, if the revealed face at time $i$ is of the form (C, 1) then we let $\epsilon_i = \frac{1}{2}$ when the revealed vertex is white and $\epsilon_i = -\frac{1}{2}$ when it is black. We set $\epsilon_i = 0$ otherwise. The description of the exploration process shows that for every $i \geq 0$ we have

$$
\eta^\text{\textit{Perc}}^-(i) = H^\text{\textit{Perc}}^-(i + 1) - H^\text{\textit{Perc}}^-(i + \frac{1}{2}) = -\epsilon_i,
$$

$$
\eta^\text{\textit{Perc}}^+(i) = H^\text{\textit{Perc}}^+(i + 1) - H^\text{\textit{Perc}}^+(i + \frac{1}{2}) = +\epsilon_i.
$$

Indeed, when the revealed face is not of the form (C, 1) then $\epsilon_i = 0$ and the next edge to peel is necessarily the unique edge of the revealed triangle belonging to the new infinite boundary (this edge is easily seen to be of type $\bullet - \circ$). However, when the revealed face is of form (C, 1) then it
has two edges belonging to the new infinite boundary and the next edge to peel is either the “left” edge of the revealed triangle if $\epsilon_i = \frac{1}{2}$ or its “right” edge if $\epsilon_i = -\frac{1}{2}$. Since the variables $\epsilon_i$ are i.i.d. bounded centered variables we deduce that

$$\frac{\epsilon_1 + \cdots + \epsilon_{[nt]}}{\sqrt{n}} \xrightarrow{n \to \infty} (B_t)_{t \geq 0},$$

where $B$ is a multiple of a Brownian motion. On the other hand, since the exploration is Markovian the increments of the horodistances between $i$ and $i + \frac{1}{2}$ are independent copies of $(\Delta^-(F), \Delta^+(F))$. We can thus combine the last display with Proposition 2 to get the desired result (notice again that the $\sqrt{n}$ scaling of the Bernoulli variables is crushed by the $n^{2/3}$ renormalization as in the proof of Proposition 2).

2.2 The Riemann surface construction

In this section we show how to associate with the UIHPT a Riemann surface that we will later use to define SLE processes on $T_{\infty,\infty}$. We follow the presentation of [18] where the authors showed that the Riemann surface associated to the UIPT (of the full plane) is conformally equivalent to $\mathbb{C}$.

Following [18], we associate with any locally finite triangulation $T$ a Riemann surface $T$ by considering each triangle of the map as a standard Euclidean equilateral triangle endowed with its distance and use the combinatorics of the map to glue the triangles between each other. Formally, we first construct a topological space by gluing triangles according to the pattern of the map; this topological space is then endowed with a Riemann surface structure using the following coordinate charts:

- for any point located in the interior of a triangle we simply see this triangle as a standard equilateral triangle (whose sides have length 1) in the complex plane and use the identity map,

- if the point belongs to an edge, then place the two adjacent triangles (there must be two different triangles since we are considering type II triangulations) next to each other in the complex plane and use again the identity map,

- if the point is located on a vertex with $d \geq 2$ adjacent equilateral triangles $t_1, t_2, \ldots, t_d$ arranged in cyclic order then we use the following chart: First if $d = 6$ we can imagine that the six equilateral triangles are arranged in the plane around the point and use the identity map. If $d \neq 6$, we use the map $z \mapsto z^{6/d}$ as coordinate, that is, the point $z = re^{it}$ for $t \in [0, \pi/3]$ and $r < 1/2$ belonging to the triangle $t_j$ is sent to $r^{6/d} \exp(\frac{6i}{d}(t + (j - 1)\pi/3))$.

It is easy to check that the coordinate changes are analytic and thus this atlas does define a Riemann structure, see [18] for details. In the language of geometers, this procedure yields an Euclidean surface with conical singularities at vertices of degree different from 6, see [45].

In the case of the UIHPT we obtain a (random) simply connected Riemann surface with a boundary denoted by $T_{\infty,\infty}$. By the classical Riemann uniformization theorem, this surface can be uniformized onto the upper half-plane $\mathbb{H} = \{z \in \mathbb{C}, \Re(z) > 0\}$, viz there exists a (random) bi-holomorphic map $T_{\infty,\infty} \to \mathbb{H}$. This map is unique and denoted by $\phi_{T_{\infty,\infty}}$ provided that we fix the images of three points: the origin of the root edge is sent to $-1/2$, its target to $1/2$ and the infinity of $T_{\infty,\infty}$ is sent to the infinity of $\mathbb{H}$. The image of the edges of $T_{\infty,\infty}$ in $T_{\infty,\infty}$ under this conformal map is thus a canonical proper embedding of $T_{\infty,\infty}$ in $\mathbb{H}$ and is denoted by $\mathcal{T}_{\infty,\infty}$. It
should be considered as a canonical and conformally “faithful” representation of the UIPT of the half-plane, see Fig. 2.

Once we have constructed this canonical representation of the UIHPT, one can consider various stochastic processes on it. For example we can define a Brownian motion (up to time parametrization) moving over $T_{\infty, \infty}$ (more precisely over $T_{\infty, \infty}$) as the pre-image under $\phi_{T_{\infty, \infty}}$ of a standard reflected Brownian motion on $\mathbb{H}$. The goal of the next subsection is to study one very special random process over $T_{\infty, \infty}$: the SLE process of parameter $\kappa = 6$.

2.3 SLE$_6$ exploration

We recall the definition of the chordal SLE$_6$ in the upper half-plane. The reader is referred to [27] for details and proofs. Let $B_t$ be a standard linear Brownian motion and consider the flow of conformal mappings obtained by solving the following PDE:

$$\partial_t g_t(z) = \frac{2}{g_t(z) - \sqrt{6}B_t}, \quad g_0(z) = z. \quad (16)$$

For each $t \geq 0$, the function $g_t$ maps a certain simply connected domain $H_t \subset \mathbb{H}$ onto the upper half-plane $\mathbb{H}$. Furthermore, it is by now classical that $\mathbb{H} \setminus H_t$ can be represented as the hull of a random curve $\gamma : \mathbb{R}_+ \rightarrow \mathbb{H}$ starting from 0, that is

$$H_t = \text{infinite open component of } \mathbb{H} \setminus \gamma([0, t]).$$

This curve is called the Schramm–Loewner curve of parameter $\kappa = 6$ abbreviated by SLE$_6$. It enjoys the following scaling property: $(\gamma_t : t \geq 0) = \lambda^{-1/2}(\gamma_{\lambda t} : t \geq 0)$ in distribution for all $\lambda > 0$. It is also known that for $\kappa = 6$, the SLE$_6$ is not a simple curve (it touches itself) and furthermore bounces on the real axis infinitely many often.

![Figure 12: Simulation of an SLE$_6$ in the half-plane, courtesy of Vincent Beffara. On top of it, the uniformization of a UIHPT.](image)

Independently of $T_{\infty, \infty}$, consider a standard SLE$_6$ curve $(\gamma_t)_{t \geq 0}$ on $\mathbb{H}$ started from 0. We define the SLE$_6$ on the (Riemann surface associated to the) half-plane UIPT as the path

$$(\phi_{T_{\infty, \infty}}^{-1}(\gamma_t))_{t \geq 0}. \quad (17)$$
Although this process runs over the Riemann surface $T_{\infty,\infty}$, one will abuse notation and say that the SLE$_6$ explores the UIHPT itself and that $\gamma$ is running directly over $T_{\infty,\infty}$. One can thus make sense of the discrete notion of face, edge or point of $T_{\infty,\infty}$ visited by the SLE$_6$.

In the following, “exploration of the UIHPT” will always refer to the above SLE$_6$ exploration.

Let us begin with a few remarks concerning this process. Since the points are polar sets for the SLE$_6$ on $\mathbb{H}$, it follows that the curve $\gamma$ on the UIHPT almost surely does not visit the vertices of $T_{\infty,\infty}$ (this is why we uniformized the root edge onto $[-\frac{1}{2}, \frac{1}{2}]$ and not onto $[0, 1]$). The SLE$_6$ defines an (a priori non-Markovian) exploration of the half-plane UIPT: For any $t \geq 0$, we denote by Hull$(t)$ the subtriangulation of $T_{\infty,\infty}$ obtained by the union of all the faces visited by the curve $\gamma$ before time $t$ as well as the finite regions they enclose. The growing subtriangulations $\{\text{Hull}(t)\}_{t \uparrow}$ are then naturally associated with an (a priori non-Markovian) exploration process of $T_{\infty,\infty}$. After forgetting the continuous time parametrization, we denote by $(a_i)_{i \geq 0}$, $(K_i)_{i \geq 0}$, $(T_i)_{i \geq 0}$, $(H^-(i), H^+(i))_{i \geq 0}$ the sequences of peeled edges, explored and remaining parts, and horodistances in this exploration. Note that we used only the curve $\gamma$ up to time parametrization to define this exploration. Finally, we denote by $\mathcal{F}_{n}$ the $\sigma$-field generated by the knowledge of the part $K_n$ at (the discrete) time $n$ as well as the curve $\gamma$ restricted up to the first visit of a face not in $K_n$ (whose tip is thus located on $a_n$).

### 2.4 Locality of SLE$_6$ and the spatial Markov property

Remark that one could have considered other explorations (on the Riemann surface) of $T_{\infty,\infty}$ using different SLE$_\kappa$ curves by mimicking the definition (17). However, the SLE of parameter $\kappa = 6$ plays a very special role since it defines a Markovian exploration in the sense of Definition 2. Let us explain this crucial point in more details.

A characteristic property of the SLE$_6$ process that it shares with Brownian motion is the locality property, see [27, Section 6.3]. This property is reminiscent of the fact that the SLE$_6$ is the scaling limit of site percolation interface on the triangular lattice [43] and loosely speaking means that the SLE$_6$ curve does not feel the boundary of the domain it explores before it touches it. A key consequence for us is the following : Although the definition of the SLE$_6$ over $T_{\infty,\infty}$ given via (17) a priori depends on the Riemann uniformization of the UIHPT, the locality property enables us to define the curve $\gamma$ (up to time reparametrization) running over $T_{\infty,\infty}$ by discovering the UIHPT “step-by-step” and revealing only the parts necessary for the SLE$_6$ to displace.

More precisely, fix a finite triangulation $K$ with a simple boundary having a distinguished segment $S$ of boundary edges not containing the root edge; and let $T$ be an infinite triangulation with an infinite boundary. We consider the triangulation $K + T$ obtained by gluing $T$ on the segment of $K$ and keeping the root of $K$. After uniformizing this triangulation onto $\mathbb{H}$ as in Section 2.3 we consider an independent SLE$_6$ curve $\gamma$ running on $K + T$. We denote by $\gamma|_K$ the curve $\gamma$ seen up to time-reparametrization and running over the Riemann surface $K + T$ associated to $K + T$ until the first hitting of an edge of $S$, see Fig. 13.

**Lemma 4.** The law of $\gamma|_K$ does not depend on $T$. In other words, the evolution of the SLE$_6$ inside $K$ can be performed without requiring the information outside $K$. 

19
Proof. Consider two infinite triangulations with infinite boundary \( T \) and \( T' \). After forming the two gluings of \( K \) with \( T \) and \( T' \) along \( S \), uniformize these two maps onto \( \mathbb{H} \) by sending the root edge to \([-1/2, 1/2]\) and \( \infty \) to \( \infty \), see Fig. 13.

![Figure 13: Rephrasing the locality property in our context.](image)

In these uniformizations, the images of \( K \) thus forms two different \( \mathbb{H} \)-neighborhoods\(^3\) \( N_1 \) and \( N_2 \) of the origin (in gray in Fig. 13), see [27, Chapter 6.3]. The composition of the uniformizing maps thus yields a locally real\(^4\) conformal transformation \( f_{T,T'} \) sending \( N_1 \) to \( N_2 \). The locality property of the SLE\(_6\) [27, Theorem 6.13] precisely tells us that the image of an SLE\(_6\) curve in \( N_1 \) has the law of an SLE\(_6\) in \( N_2 \). Otherwise said, the image of the SLE\(_6\) running on the uniformization of \( K + T \) and stopped when touching (the image of) \( S \), once pushed by \( f_{T,T'} \), is an SLE\(_6\) exploring \( K + T' \) stopped when touching \( S \). The statement of the lemma follows.

A repetitive use (safely left to the reader) of the last lemma indeed shows that the edge to peel at time \( i \geq 0 \) is independent of the remaining part \( T_i \) and so:

**Corollary 5.** The exploration process of \( T_{\infty, \infty} \) induced by the SLE\(_6\) is Markovian.

### 2.5 The (\( \ast \)) property

The goal of this section is to introduce the condition \( \ast \) under which the scaling limit of the horodistance processes is known. Although we have been unable to prove it, we will try to convince the reader it is true, see Section 5. Recall the notation

\[
\mathcal{H}^-(i+1) - \mathcal{H}^-(i + \frac{1}{2}) = \eta_i^-, \quad \text{and} \quad \mathcal{H}^+(i+1) - \mathcal{H}^+(i + \frac{1}{2}) = \eta_i^+.
\]

Our hypothesis \( \ast \) on which most of the interesting results of this paper rely is

\[
\sup_{t \in [0,1]} \eta_1^+ \eta_2^+ \cdots \eta_{\lceil tn \rceil}^+ \sim \frac{(P)}{n^{2/3}} \quad \text{as} \quad n \to \infty
\]

where \((P)\) denotes convergence in probability.

---

\(^3\) An open subset \( \mathcal{N} \subset \mathbb{H} \) is a \( \mathbb{H} \)-neighborhood of \( x \) if \( B(x, \varepsilon) \cap \mathbb{H} \subset \mathcal{N} \) for some \( \varepsilon > 0 \), see [27, Section 4.6].

\(^4\) A univalent function \( \phi : \mathcal{N} \to \mathbb{H} \) is locally real at \( x_0 \) if \( \phi(z) = a_0 + a_1(z-x_0) + a_2(z-x_0)^2 + \cdots \) locally around \( x_0 \) with \( a_0, a_1, a_2, \ldots \in \mathbb{R} \), see [27, Section 4.6].
Theorem* 2. We have the following convergence in distribution
\[
\left( \frac{\mathcal{H}^+([nt]/2)}{n^{2/3}}, \frac{\mathcal{H}^-([nt]/2)}{n^{2/3}} \right) \xrightarrow{(d)_{n \to \infty}} 3^{-2/3} \cdot (S^+_t, S^-_t)_{t \ge 0}
\]
in the Skorokhod sense where \((S^+, S^-)\) is a pair of independent standard \(\frac{3}{2}\)-stable processes.

Remark 2. This theorem* has to be compared with Theorem 3. In some sense, it says that the SLE\(_6\) indeed is the scaling limit of critical percolation interfaces in the UIHPT, at least from the horodistances point of view (see Smirnov [43] for a much stronger statement in the case of the regular triangular lattice). See also Section 5 for comments and open questions.

Proof*. By Corollary 5 the SLE\(_6\) exploration is Markovian and so by Proposition 1 the variations of the horodistances between \(i\) and \(i + \frac{1}{2}\) are independent and distributed as \((\Delta^-(F), \Delta^+(F))\). By Proposition 2, we thus have
\[
n^{-2/3} \cdot \left( \sum_{i=0}^{[nt]} \mathcal{H}^- (i + \frac{1}{2}) - \mathcal{H}^- (i), \sum_{i=0}^{[nt]} \mathcal{H}^+ (i + \frac{1}{2}) - \mathcal{H}^+ (i) \right) \xrightarrow{(d)_{n \to \infty}} 3^{-2/3} \cdot (S^+_t, S^-_t)_{t \ge 0}.
\]
The condition (*) then precisely entails that the increments between \(i + 1/2\) and \(i + 1\) cannot perturb the scaling limit. More precisely, since \(\eta^+_i = -\eta^-_i\) by (10), condition (*) implies
\[
n^{-2/3} \cdot \left( \sum_{i=0}^{[nt]} \mathcal{H}^- (i + 1) - \mathcal{H}^- (i + \frac{1}{2}), \sum_{i=0}^{[nt]} \mathcal{H}^+ (i + 1) - \mathcal{H}^+ (i + \frac{1}{2}) \right) \xrightarrow{(d)_{n \to \infty}} 0,
\]
in probability for the Skorokhod topology. Combining the last two displays we have proved the theorem* when \([2nt]/2\) is replaced by \([nt]\). To get the full statement, notice that condition (*) together with (10) also implies that \(n^{-2/3} \cdot \sup_{t \le n} \eta^+_i \to 0\) in probability (see also Proposition 6 below for a stronger statement not depending on (*)).

Remark 3. At this point, the cautious reader may wonder why we have not chosen to explore the UIHPT using a Brownian motion instead of an SLE\(_6\). Indeed, Brownian motion also enjoys the locality property and hence produces a Markovian exploration. The problem is that, contrary to the SLE\(_6\), from time to time two consecutive peeling points for the Brownian motion may be far apart (in terms of horodistance): this occurs when the Brownian motion dive deep into the explored part so that the next peeling point is almost uncorrelated with the preceding one. Clearly, the analogous of condition (*) for the Brownian exploration of \(T_{\infty, \infty}\) does not hold and understanding the behavior of the horodistances is a very difficult problem.

2.6 Tail bound for the \(\eta^+_i\)

Although the collective behavior of the \(\eta^+_i\) is the content of the condition (*) and remains conjectural, one can establish almost exponential bounds on the tails of the \(\eta^+_i\).

Proposition 6 (Bounds for the \(\eta^+_i\)). For \(i \ge 0\), denote by \(D_i\) the maximal degree of a vertex in \(K_i\) within distance 2 of its exposed boundary (that is the boundary in common with \(T_i\)). There exist some constants \(c_1, c_2 > 0\) such that for every \(i \ge 0\) and every \(k \ge 1\)
\[(i) \quad P(D_i \ge k) \le ic_1 \exp(-c_2 k),\]
\[(ii) \quad P(D_i \ge k) \le \frac{1}{k^2} \exp(-c_1 k).\]
(ii) conditionally on $F_i$, we have $P(|\eta^+_i| \geq k) \leq c_1 \exp(-c_2 kD^{-4})$.

(iii) Consequently we have for every $\varepsilon > 0$

$$\lim_{n \to \infty} \sup_{i \leq n} \frac{|\eta^+_i|}{\log^{\varepsilon + \varepsilon} n} = 0.$$ 

Proof of Proposition 6. (i). This statement should not be surprising for experts since it is more-or-less folklore than the maximal degree in a random triangulation is logarithmic in its size, see [7, Lemma 4.2] and [9, Proposition 12] for similar statements. However, we give a full proof for completeness. First of all, an easy adaptation of [7, Lemma 4.2] to the case of the UIHPT shows that the degree of the origin of the root edge in $T_{\infty,\infty}$ has an exponential tail. Actually, a slight generalization of it (left to the reader) shows that the maximal degree of a vertex within distance 3 of the root edge $e$ of $T_{\infty,\infty}$ (that is of one of its extremities) also has an exponential tail, namely there exist $c_1, c_2 > 0$ such that for every $k \geq 0$

$$P\left( \exists v \in T_{\infty,\infty}, d_{\text{gr}}^{T_{\infty,\infty}}(v,e) \leq 3 : \deg(v) \geq k \right) \leq c_1 e^{-c_2 k},$$

where the notation $d_G^{gr}$ stands for the graph distance in the graph $G$. Next, for $i \geq 1$ if $v$ is a vertex of $K_i$ within distance 2 of its exposed boundary, then if $j = \inf\{n \leq i : v \in K_n\}$ is the first time at which $v$ is discovered (note that since $K_0 = \emptyset$ we have $j \geq 1$), then $v$ is necessarily a vertex of $T_{j-1}$ and an easy geometric argument shows that

$$d_{\text{gr}}^{T_{j-1}}(v,a_{j-1}) \leq 3.$$ 

Recall from Proposition 1 that for a Markovian exploration process, for every $j \geq 0$ the unexplored part $T_j$ rooted at $a_j$ is distributed as a standard UIHPT. By the union bound and (18) we thus have

$$P(D_i \geq k) \leq P\left( \exists v \in T_{\infty,\infty}, d_{\text{gr}}^{T_i}(v,a_j) \leq 3 \text{ for some } 0 \leq j \leq i : \deg(v) \geq k \right) \leq i P\left( \exists v \in T_{\infty,\infty}, d_{\text{gr}}^{T_{\infty,\infty}}(v,e) \leq 3 : \deg(v) \geq k \right) \leq i c_1 e^{-c_2 k}.$$

(ii) We only give a detailed sketch and leave the precise details to the careful reader. Imagine the situation just after having peeled the $i$th edge. Let $k \geq 1$ (large) and let us evaluate the probability that the next edge to peel is the $k$th edge on the left of the root of the triangulation $T_{i+1}$. Since all the triangles that share an edge with the boundary of $T_i$ have been visited by the SLE$_6$ process, that means that the curve $\gamma$ has to travel in a narrow region towards the left to finally exit at the desired edge while bumping on its past and without touching any edge on the boundary of $T_{i+1}$ during its journey. See Fig. 14.

In particular, we can define a “channel” as being the region separating the target edge from the current position of the SLE with two edges playing the role of the entry and exit of the channel, see Fig. 15. To show the bound of the proposition, we will prove that the probability that an SLE$_6$ crosses the channel without touching the above boundary edges is very low. This is intuitively clear since the latter is a narrow and long path (when $k$ is large), but what really matters is its conformal width.

More precisely, we consider the Riemann surface $C$ associated to the channel made by the parts of the triangles that are not contained in the hull of the SLE$_6$, see Fig. 15. By the Riemann
uniformization theorem, we can map $\mathcal{C}$ onto a rectangle where the vertical sides correspond to the entry and exit of the channel. Then by standard properties, the probability that an SLE$_6$ process crosses such a rectangle without touching its above boundary is at most $c_1 \exp(-c_2 L)$ where $c_1, c_2 > 0$ and $L$ is the ratio (which does not depend on the uniformization) of the horizontal length by the vertical length of the rectangle also called the extremal length or conformal moduli. The statement of the proposition thus reduces to show that the extremal length of the channel is at least

$$L \geq c \frac{k}{D_i^4},$$

(19)

for some constant $c > 0$.

For this we use the definition of the extremal length of the channel $\mathcal{C}$ which is seen as a gluing of parts of equilateral triangles and thus endowed with the locally Euclidean metric and measure. If $\rho : \mathcal{C} \to \mathbb{R}_+$ is a positive function (also called “metric”) we let $\text{Area}(\rho)$ be the integral of $\rho^2$ with respect to the Lebesgue measure on $\mathcal{C}$. Also, if $\Gamma$ is a smooth path going from the Entry to the Exit of the channel, we define the $\rho$-length of $\Gamma$ as

$$\text{Length}_\rho(\Gamma) = \int_\Gamma |ds| \rho,$$

where $|ds|$ denotes the Euclidean element of length. With this piece of notation, the extremal length $L$ of $\mathcal{C}$ is expressed as (see [1, Chapter 4])

$$L = \sup_\rho \inf_\Gamma \left( \frac{\text{Length}_\rho(\Gamma)^2}{\text{Area}(\rho)} \right),$$

(20)

where the supremum is taken over all “metrics” $\rho : \mathcal{C} \to \mathbb{R}_+$ and the infimum runs over all rectifiable paths joining Entry to Exit in the channel. To show (19) we consider a particular metric $\rho_0$ defined
as follows: the function $\rho_0$ is constant and equals to 1 on every (part of) triangle of $\mathcal{C}$ which contains a vertex at combinatorial distance less than 1 from the above boundary of the channel. Otherwise $\rho_0 = 0$ on the rest of the channel. Because $D_i$ is the maximum vertex degree within distance 2 of the exposed boundary of $K_i$ we have

$$\text{Area}(\rho_0) \leq \frac{\sqrt{3}}{4} \cdot (k + 1) \cdot D_i^2.$$  (21)

We now have to bound from below the $\rho_0$-length of a smooth path crossing $\mathcal{C}$. To do so, we will identify a combinatorial pattern in the channel that requires a minimal $\rho_0$-length to be traversed. First notice that all the combinatorial triangles adjacent to the above boundary of the channel are either pointing upwards $\Delta$ or downwards $\nabla$. An block is a sequence $\nabla, \Delta, \ldots, \Delta, \nabla$ together with the triangles “grafted” on the bottom of the upwards triangles. See Fig. 16.

![Figure 16: A block requires a minimal $\rho_0$-length to be crossed.](image)

As already mentioned, all the downwards triangles $\nabla$ contain a piece of the curve $\gamma$ for otherwise they would not have been discovered. An easy geometrical argument shows that the $\rho_0$-length needed to cross a block is lower bounded by some universal constant $c' > 0$. Hence, the minimal $\rho_0$-length of a curve $\Gamma$ crossing the channel is at least $c'$ times the number $B$ of blocks of this channel. However, it is easy to see that

$$B \geq \frac{k}{10D_i},$$

which combined with (21) and the definition (20) of $L$ finishes the proof of the (ii).

(iii) For the final item we have using (i) and (ii)

$$P(|\eta_i^+| \geq \log^{5+\varepsilon} i) \leq P(D_i \geq \log^{1+\varepsilon/5} i) + P(|\eta_i^+| \geq \log^{5+\varepsilon} i \mid D_i \leq \log^{1+\varepsilon/5} i)$$

$$\leq ic_1 e^{-c_2 \log^{1+\varepsilon/5} i} + c_1 e^{-c_2 \log^{1+\varepsilon/5} i}.$$ 

The right-hand side is obviously summable in $i$ and so an application of Borel–Cantelli’s lemma finishes the proof of the proposition. \hfill \Box

3 Bouncing off the walls

The basic idea of Theorem* 1 is the following: When the horodistance $\mathcal{H}^+$ (resp. $\mathcal{H}^-$) reaches a new minimum value, this geometrically corresponds to a visit of $\mathbb{R}^+$ (resp. $\mathbb{R}^-$) by the SLE curve $\gamma$. This heuristic is not exact on a discrete level but becomes true in the limit (see Proposition* 3). This enables us to relate the number of alternative visits to $\mathbb{R}^+$ and $\mathbb{R}^-$ by the curve $\gamma$ in terms of alternative minimal records of $S^+$ and $S^-$ (Proposition 8).
3.1 Discrete bouncing

For any $n \geq 0$, we introduce the first time $\tau^+(n)$ after $n$ such that the peeling of the edge $a_{\tau^+(n)}$ discovers a triangle of form $(D, \cdot)$ whose third vertex is lying on the original boundary of $T_{\infty, \infty}$.

Equivalently, using (11) we have

$$
\tau^+(n) = \inf \left\{ k \geq n : H^+ \left( k + \frac{1}{2} \right) = H^+(k) \right\}.
$$

The quantity $\tau^-(n)$ is defined by similar means. Thanks to Theorem 2 and since $\liminf S^+ = \liminf S^- = -\infty$ we have $\tau^+(n) < \infty$ and $\tau^-(n) < \infty$ almost surely for every $n \geq 0$.

Lemma 7 (Discrete bouncing). There exists some constant $c > 0$ such that for every $n \geq 0$, conditionally on \{$\tau^+(n) = N$\} and on $F_N$, there is a probability at least $c$ that $\gamma$ touches $\mathbb{R}_+$ within the next three peeling steps.

Obviously, a similar lemma holds when “+” is replaced by “−”.

Proof. Fix $n \geq 0$ and suppose that $\tau^+(n) = N < \infty$. At time $N$ the peeled triangle of form $(D, \cdot)$ has thus “swallowed” all the exposed boundary of $K_N$ on the right of $a_N$. If $(F_i)_{i \geq 0}$ denote the forms of the triangles peeled, the event we now consider is the following (see Fig. 17 and recall Fig. 7):

$$
E_N = \left\{ \begin{array}{l}
\eta^+_N = 0, \eta^+_{N+1} = 0, F_{N+1} = (D, -1), F_{N+2} = (G, -1), \\
\text{and the associated enclosed triangulations of perimeter 2}
\end{array} \right\}.
$$

Figure 17: Illustration of the proof.

In words, on this event the SLE$_6$ first exists towards the only exposed edge of the triangle discovered at time $N$ and discovers a triangle “glued” to the explored part on the right, then exists towards the exposed edge of this triangle and discovers a triangle glued to the explored part on the left. It should be clear that conditionally on $F_N$, the last event has a probability bounded away from 0 and that conditionally on $E_N$ the path $\gamma$ touches the real axis between time $N$ and $N + 3$ with positive probability. We leave the details to the reader.

Commutings. We will now describe the limit as $n \to \infty$ of the random times $\tau^+(n)$ using the scaling limit of the horodistance processes given by Theorem 2. Recall that $S^+$ and $S^-$ are two independent standard $\frac{3}{2}$-stable processes with only negative jumps. We denote by

$$
S^+_u = \inf \{ S^+_u : 0 \leq u \leq t \} \quad \text{and} \quad S^-_u = \inf \{ S^-_u : 0 \leq u \leq t \}
$$

25
be the running infimum processes of $S^+$ and $S^-$. For every $t \geq 0$ introduce

$$\xi^+(t) = \inf \{ u \geq t : S^+_u = S^+_t \},$$

and put a similar definition for $\xi^-(t)$. By standard properties of the spectrally negative $\frac{3}{2}$-stable process, for every $t > 0$ we have $\xi^+(t) > t$ almost surely. Furthermore the time $\xi^+(t)$ a.s. corresponds to a jump of the process which reaches a strict new minimum, that is

$$S^+_t > S^+_{\xi^+(t)}.$$  \hfill (23)

Using standard properties of the Skorokhod topology [21, Chapter VI], we deduce from the above display, (22) and Theorem* 2 that for every $t > 0$ we have the following convergence in distribution

$$\frac{\tau^+([nt])}{n} \xrightarrow{n \to \infty} \xi^+(t),$$

and similarly when “+” is replaced by “−”. We denote by

$$\mathcal{R}^+ = \{ t \geq 0 : S^+_t = S^+_t \} \quad \text{and} \quad \mathcal{R}^- = \{ t \geq 0 : S^-_t = S^-_t \}$$

the set of times corresponding to minimal records of the processes $S^+$ and $S^-$. These two random closed sets are a.s. perfect (not isolated points), also it is known that we almost surely have

$$\mathcal{R}^+ \cap \mathcal{R}^- = \{ 0 \},$$

see [13, Chapter 5]. The last display entails that for every $k \in \{0, 1, 2, \ldots\}$ the $k$th alternate composition

$$\xi^{(k)} = \xi^+ \circ \cdots \circ \xi^+ \circ \xi^- \circ \xi^+,$$

is well-defined and that we have $t < \xi^{(1)}(t) < \xi^{(2)}(t) < \cdots$ as well as $\xi^{(n)}(t) \to \infty$ for every $t > 0$ as $n$ goes to infinity. Note that for any $t > 0$, by the scaling property of the stable processes we have the following equality in distribution

$$\left( \xi^{(k)}(t) \right)_{k \geq 0} = t \cdot \left( \xi^{(k)}(1) \right)_{k \geq 0}. \hfill (25)$$

We will later study the behavior of $\xi^{(n)}(1)$ as $n \to \infty$, see Proposition 8. In the spirit of (23) one can check that $\xi^{(k)}(t)$ is a jump time of $S^\pm$ (depending on the parity of $k$) that reaches a strict new minimum a.s. We mimic the definition of $\xi^{(k)}$ and set $\tau^{(k)}$ to be the $k$th alternate composition

$$\tau^{(k)} = \tau^+ \circ \cdots \circ \tau^+ \circ \tau^- \circ \tau^+.$$  \hfill (26)

The above considerations show that Theorem* 2 actually leads to the following extension of (24): for every $t > 0$ we have the following convergence in distribution

$$\frac{\tau^{(k)}([nt])}{n} \xrightarrow{n \to \infty} \left( \xi^{(k)}(t) \right)_{k \geq 0}.$$
Section 2.3 that $(\gamma_t)_{t \geq 0}$ is a standard chordal SLE$_6$ on $\mathbb{H}$ starting from 0 and parametrized by its half-plane capacity. In accordance to the above notation, for every $t \geq 0$ we put

$$\theta^+(t) = \inf \{ s \geq t : \gamma_s \in \mathbb{R}_+ \},$$

where an obvious definition holds for $\theta^-$. Here also, for every $k \geq 0$ we denote by $\theta^{(k)}$ the $k$th alternated composition $\theta^+ \circ \ldots \circ \theta^- \circ \theta^+$. Again, the scaling property of the SLE process implies that

$$(\theta^{(k)}(t))_{k \geq 0} = t \cdot (\theta^{(k)}(1))_{k \geq 0}$$

in distribution for every $t > 0$. Proposition 12 studies the behavior of $\theta^{(n)}(1)$ as $n \to \infty$.

When the SLE$_6$ curve $\gamma$ is used to explore the half-planar triangulation $T_{\infty, \infty}$ we will need to tie the continuous parametrization of the curve $\gamma$ to the discrete exploration steps. If $t_i$ for $i = 0, 1, 2, \ldots$ are the continuous times at which the $i$th edge to peel is discovered by the SLE process then for every $k, i \in \{0, 1, 2, \ldots\}$ we let

$$\tilde{\theta}^{(k)}(i) = \inf \{ j \geq 0 : \theta^{(k)}(t_i) \leq t_j \}.$$

As promised in the introduction of this section, we prove that the scaling limit of the alternative bouncing on $\mathbb{R}_+$ and $\mathbb{R}_-$ by the SLE are described by the alternative minimal records of the processes $S^+$ and $S^-$. More precisely, we have

**Proposition** 3 (Connecting $\theta$ and $\tau$). For every $k \geq 1$ we have

$$\tilde{\theta}^{(k)}(n) \overset{(P)}{\to}_{n \to \infty} 1.$$

**Proof.** **Upper bound.** Fix $n \geq 0$ (large). Conditionally on the past exploration before $\tau^+(n)$ there is a positive probability that $\gamma$ touches $\mathbb{R}_+$ between the peeling steps $\tau^+(n)$ and $\tau^+(n)+3$ by Lemma 7. We claim that in fact, the SLE curve will hit $\mathbb{R}_+$ between the peeling steps $\tau^{(1)}(n) = \tau^+(n)$ and $\tau^{(2)}(n) = \tau^- (\tau^+(n))$ with a probability tending to 1 as $n \to \infty$.

Indeed, by standard properties of the stable process, the time $\xi^+(1) \in \mathcal{R}^+$ is not isolated from the right in $\mathcal{R}^+$. Using (23) and standard properties of the Skorokhod topology, it follows from Theorem 2 that for any $p \geq 0$ we have

$$\frac{\tau^+, (p)(n) - \tau^+(n)}{n} \overset{(P)}{\to}_{n \to \infty} 0,$$

where $\tau^+, (p)$ is the $p$-fold composition of $\tau^+$. Since $n^{-1} \tau^{(2)}(n)$ converges in distribution towards $\xi^{(2)}(1) > \xi^+(1)$, for any $p \geq 1$, with high probability as $n \to \infty$, we can find $p$ times between $\tau^+(n)$ and $\tau^- (\tau^+(n))$ where $\mathcal{H}^+(i + 1/2) = \mathcal{H}^+(i)$. Applying successively Lemma 7 to these times, we deduce that with high probability the SLE curve touches $\mathbb{R}_+$ after the step $\tau^+(n)$ but before step $\tau^{(2)}(n)$. An easy extension of the above argument then yields

$$P \left( \tilde{\theta}^{(k)}(n) \leq (1 + \varepsilon)\tau^{(k)}(n) \right) \overset{n \to \infty}{\longrightarrow} 1,$$

for any $k \in \{1, 2, \ldots\}$ and any $\varepsilon > 0$.

**Lower bound.** Assume that at time $t \geq 0$ we have $\gamma_t \in \mathbb{R}_+$. Intuitively the next edge to peel will be close to the extreme-right edge of the explored part, that is with a minimal horodistance.

27
Indeed, an easy adaptation of the proof of Proposition 6 shows that the next edge to peel \( a_i \) has a horodistance \( H^+(i) \) close to \( H^+(i-1) \) in the sense that asymptotically we have

\[
\frac{H^+(i) - H^+(i-1)}{\log^{\frac{1}{i+\varepsilon}}i} \leq 1.
\]

Since by Theorem* 2, \( H^+(i-1) \) is of order \( i^{2/3} \) that means that \( H^+(i) \) is very close to its past infimum. Since the set of minimal records of a \( 3/2 \)-stable process has no isolated point, using standard properties of stable processes and Theorem* 2 again we deduce that for any \( \varepsilon > 0 \) with high probability there exists \( (1-\varepsilon) \leq j \leq (1+\varepsilon)i \) such that \( H^+(j) = H^+(j+1/2) \). Iterating this argument we get that

\[
P\left( \tau(k)(n) \leq (1+\varepsilon)\hat{\theta}(k)(n) \right) \xrightarrow{n \to \infty} 1,
\]

for any \( k \in \{1, 2, \ldots\} \) and any \( \varepsilon > 0 \). Combining this display with the upper bound previously obtained completes the proof of the proposition*.

The next two sections are devoted to two computations which investigate the behavior of \( \theta(n)(1) \) and \( \xi(n)(1) \) as \( n \to \infty \). These are technical propositions and their proofs can be skipped at first reading. This piece of information, combined with Proposition* 3 is the heart of the proof of Theorem* 1. Since we will heavily deal with large deviations estimates we introduce a special notation for it.

**A notation for large deviations.** Let \( I = \mathbb{Z}_+, \mathbb{R}_+ \) or \( (0, 1) \) and \( \omega \in \{0, \infty\} \). If a real stochastic process \( (X_i)_{i \in I} \) indexed by \( I \) satisfies a weak law of large numbers:

\[
\lim_{i \to \omega} \frac{X_i}{f(i)} = K,
\]

in probability for some function \( f \) such that \( |f| \to \infty \) as \( i \to \omega \) (e.g. \( f(i) = i \) or \( f(i) = \log i \)) and some constant \( K \in \mathbb{R} \), we will say that large deviations hold if for every \( \eta > 0 \) there exist \( c_1, c_2 > 0 \) (which depend on \( \eta \)) such that for all \( i \in I \) sufficiently close to \( \omega \) we have

\[
P\left( \left| \frac{X_i}{f(i)} - K \right| > \eta \right) \leq c_1 e^{-c_2|f(i)|},
\]

and we write

\[
\limLD_{i \to \omega} (X_i, f(i)) = K.
\]

Let us give a few examples. The most basic one is to consider a sequence \( \zeta_1, \ldots, \zeta_n \) of i.i.d. random variables such that \( E[\exp(\lambda|\zeta|)] < \infty \) for some \( \lambda > 0 \). Then by classical results on large deviations, their partial sums \( S_n = \zeta_1 + \cdots + \zeta_n \) satisfy

\[
\limLD_{n \to \infty} (S_n, n) = E[\zeta].
\]

Various other examples will arise in this work and are based on scale invariance. E.g., consider the \( \frac{3}{2} \)-stable process \( S^+ \) and its infimum process \( \underline{S}^+ \). For any \( t > 0 \), by the scaling property we have \( \underline{S}^+_t = t^{2/3} \underline{S}^+_1 \). Also, by standard properties, the law of \( \underline{S}^+_1 \) has a polynomial tail as \( t \to -\infty \) and a
bounded density around 0, thus we have \( P(\{\log -S^+_1 > x\} > \epsilon) \leq e^{-cx} \) for some \( c > 0 \) as \( x \to \infty \). For every \( \eta > 0 \) and \( t \geq 1 \) we have
\[
\begin{align*}
P\left( \left| \frac{\log -S^+_1}{\log t} - \frac{2}{3} \right| > \eta \right) &= P\left( |\log -S^+_1| > \eta \log t \right) \\
&\leq c_1 \exp(-c_2 \log t) \\
&\Rightarrow \lim_{t \to \infty} \text{LD} \left( \log |S^+_1|, \log t \right) = \frac{2}{3}. \quad (29)
\end{align*}
\]

The last display also holds if we replace \( t \to \infty \) by \( t \to 0 \). Another useful example comes from the SLE_6 curve \((\gamma_t)_{t \geq 0}\) on \( \mathbb{H} \). For any \( t > 0 \) we consider the random variable \( \gamma^+_t = \sup \{ \gamma_{[0,t]} \cap \mathbb{R}^+ \} \). By the scaling property of the SLE processes, for any \( t > 0 \) we have
\[
\gamma^+_t = 1^{1/2} \gamma^+_1
\]
in distribution. Furthermore, by standard properties \([27, \text{Chapter 6}]\) there exists \( c > 0 \) such that we have \( P(\gamma^+_1 \leq \epsilon) \leq e^{-c} \) as \( \epsilon \to 0 \) as well as \( P(\gamma^+_1 \geq x) \leq x^{-c} \) as \( x \to \infty \). Using the same proof as above we deduce that
\[
\lim_{t \to \infty} \text{LD} \left( \log \gamma^+_t, \log t \right) = \frac{1}{2}. \quad (30)
\]

Again, the last display holds when \( t \to 0 \) instead of \( t \to \infty \).

### 3.2 A \( \frac{3}{2} \)-stable calculation: estimates for \( \xi^{(n)} \)

Recall the definition of \( \xi^{(n)}(t) \) from Section 3.1. In order to lighten notation, in this section we put \( \xi^{(n)} := \xi^{(n)}(1) \) for every \( n \geq 0 \).

**Proposition 8.** We have \( \lim_{n \to \infty} \text{LD} \left( \log \xi^{(n)}, n \right) = \frac{\pi}{\sqrt{3}}. \)

Before starting the proof, let us recall some useful facts about \( \frac{3}{2} \)-stable processes. We refer to \([12, 13]\) for the derivations of these classical identities. Let \( S \) be a standard \( \frac{3}{2} \)-stable Lévy process with no positive jumps and let \( S \) be its running infimum process. The reflected process \( S - \frac{3}{2} S \) admits a local time at 0 denoted by \( (L_t)_{t \geq 0} \). Its right-continuous inverse \( L^{-1} \) is a \( \frac{1}{2} \)-stable subordinator \(([12, \text{Chap. VIII, Lemma 1}]) \) and thus follows the generalized arcsine law \(([12, \text{Chap. III, Theorem 6}]) \): For every \( x > 0 \)
\[
x^{-1} \sup \{ t \leq x : S_t = S_x \} \overset{(d)}{=} \frac{\sqrt{3}}{2\pi} s^{-2/3} (1 - s)^{-1/3} ds 1_{(0,1)}(s). \quad (31)
\]

Recall that a random closed set \( S \subset \mathbb{R}_+ \) such that almost surely \( S \) is not bounded, has no isolated point and such that \( 0 \in S \) is a regenerative set if for any \( t \geq 0 \), conditionally on \( Z_t = \min[t, \infty) \cap S \), the set \( (S \cap [X_t, \infty)) - X_t \) is independent of \( (S \cap [0, Z_t]) \) and is distributed as \( S \). Any regenerative set can be seen as the range of a subordinator unique up to multiplicative constant, see \([13]\). A regenerative set is thus characterized by a drift parameter \( d \geq 0 \) and a positive Lévy measure \( \pi \) (called the regenerative measure) unique up to multiplication by the same constant.

In our case, the random closed set \( \mathcal{R} = \{ t \geq 0 : S_t = S_x \} \) is a regenerative set (it corresponds to the range of the subordinator \( L^{-1} \)) with no drift and regenerative measure
\[
x^{-4/3} 1_{x > 0} dx. \quad (32)
\]

For every \( t > 0 \), almost surely \( t \notin \mathcal{R} \) and \( \mathcal{R} \) has Hausdorff dimension 1/3. Also recall from \([13, \text{Chap. 5}]\) that the intersection of two independent copies of \( \mathcal{R} \) is almost surely reduced to \{0\}. 

Proof of Proposition 8. Due to the logarithm in the statement of Proposition 8 it is more convenient to deal with the logarithm of $\mathcal{R}^+$ and $\mathcal{R}^-$: we set $\mathcal{L}^+ = \log(\mathcal{R}^+ \setminus \{0\})$ and $\mathcal{L}^- = \log(\mathcal{R}^- \setminus \{0\})$. Clearly we have $\mathcal{L}^+ \cap \mathcal{L}^- = \emptyset$ and $\xi^{(n)}$ is measurable with respect to $\mathcal{L}^+$ and $\mathcal{L}^-$, see Fig. 18. It turns out that $\mathcal{L}^+$ and $\mathcal{L}^-$ are again regenerative sets, but not started at 0: Let $\mathcal{L}$ be a random set having the law of $\mathcal{L}^+$ or $\mathcal{L}^-$ translated at its first positive value

$$L \overset{(d)}{=} (\mathcal{L}^+ - \inf \mathcal{L}^+ \cap [0, \infty)) \cap [0, \infty).$$

Lemma 9. The random set $\mathcal{L}$ is a regenerative set with no drift and regenerative measure

$$\nu(dx) = \frac{e^x}{(e^x - 1)^{4/3}} dx.$$  

Proof. This comes from a straightforward calculation: For every $x_0 \in \mathbb{R}^+_+$ the push-forward of the measure $\frac{dx}{x^3}$ on $\mathbb{R}^+_+$ given in (32) by the map $u \mapsto \log(u + x_0) - \log(x_0)$ is a multiple (depending of $x_0$) of the measure $\nu(dx)$. \hfill $\Box$

![Figure 18:](image)

The sets $\mathcal{L}^+$ and $\mathcal{L}^-$ and the steps of the chain $(\log \xi^{(n)})_{n \geq 0}$.

The main observation is the following.

Lemma 10. The process $X_n := \log \xi^{(n+1)} - \log \xi^{(n)}$ for $n \geq 2$ is a Markov chain with transition kernel

$$p(x, dy) = \frac{\sqrt{3}}{2\pi} \left( \frac{e^x - 1}{e^{x(y - 1)} - 1} \right)^{1/3} dy \quad 1 - e^{-x-y}.$$  

Proof. For $x > 0$ we denote by $G_x = \sup\{s \leq x : s \in \mathcal{L}\}$ and $D_x = \inf\{s \geq x : s \in \mathcal{L}\}$. Since almost surely $x \notin \mathcal{L}$, we have $G_x < x < D_x$. We denote by $p_x(dy)$ the law of $D_x - x$ and will show that $(X_i)_{i \geq 2}$ is a Markov chain with transition kernel $p(x, dy) = p_x(dy)$.

Let $i \geq 2$ be odd (say). The point $\log \xi^{(i)}$ thus belongs to $\mathcal{L}^+$. Note that $X_1, \ldots, X_{i-1}$ are measurable with respect to

$$\mathcal{F}_i := \sigma(\mathcal{L}^+ \cap [0, \log \xi^{(i)}], \mathcal{L}^+ \cap [0, \log \xi^{(i-1)}]).$$

We thus condition on $\mathcal{F}_i$ and look for the next point larger than or equal to $\log \xi^{(i)}$ belonging to $\mathcal{L}^-$. By the regenerative property of $\mathcal{L}^-$, the conditional distribution of $\mathcal{L}^- \cap [\log \xi^{(i-1)}, \infty)$ is that of $\mathcal{L} + \log \xi^{(i-1)}$ (here we use that $i \geq 2$). The conditional law of $X_i = \log \xi^{(i+1)} - \log \xi^{(i)}$ is that of the law of $D_{X_{i-1}} - X_{i-1}$. Consequently, conditionally on $X_1, \ldots, X_{i-1}$, the variable $X_i$ is distributed as $p_{X_{i-1}}(dy)$ as desired.
Let us now compute the distribution $p_x(dy)$ for $x > 0$. This is a pretty straightforward calculation but we provide the details for the reader’s convenience. We first compute the distribution of $G_x$. For this we use the arcsine law (31) on the original regenerative set $\mathcal{R}$. Indeed if $\mathcal{R}$ is a version of $\mathcal{R}$ started at time 1 then $G_x$ has the same distribution as

$$G_x \overset{(d)}{=} \log(\sup\{s \leq e^x : s \in \mathcal{R}\}).$$

The law of the random variable inside the logarithm on the right-hand side minus 1 and divided by $e^x - 1$ is the arcsine law (31) of parameter 1/3. In other words, for any positive measurable function $f$ we have

$$E[f(G_x)] = \int_0^1 ds \frac{\sqrt{3}}{2\pi} s^{-2/3}(1-s)^{-1/3} f\left(\log\left((e^x - 1)s + 1\right)\right).$$

Performing the change of variable $u = \log((e^x - 1)s + 1)$, the law of $G_x$ is finally given by

$$G_x \overset{(d)}{=} \frac{\sqrt{3}}{2\pi} \frac{e^u 1_{0<u<x}}{(e^u - 1)^{2/3}(e^u - e^a)^{1/3}} du. \quad (33)$$

Finally, conditionally on $G_x$, by the regenerative property of $L$, the law of $D_x - x$ is given by $\nu(dy | y > x - G_x)$. Using Lemma 9 (and the easy identity $\nu[x, \infty) = 3/(e^x - 1)^{1/3}$ for $x > 0$) we get that for any positive measurable $f$

$$E[f(D_x - x)]$$

$$= \int_0^x du \frac{\sqrt{3}}{2\pi} \frac{e^u}{(e^u - 1)^{2/3}(e^u - e^a)^{1/3}} \int_{x-u}^\infty da \frac{e^a}{(e^a - 1)^{4/3}} f(a - (x - u))$$

$$= \frac{1}{2\pi\sqrt{3}} \int_0^x dv \frac{e^{x-v}}{(e^{x-v} - 1)^{2/3}(e^{x-v} - e^{x-v})^{1/3}} \int_0^\infty dy \frac{e^{y+v}}{(e^{y+v} - 1)^{4/3}} f(y)$$

$$= \frac{1}{2\pi\sqrt{3}} \int_0^\infty dy f(y) \int_0^x dv \frac{e^{y+v}}{(e^{y+v} - 1)^{4/3}(e^{y-v} - e^x)^{2/3}}.$$

The last integral has been computed using Mathematica©, however it is easy (but tedious) to check a posteriori that it is equal to the formula provided in the statement of the lemma.

Using the exact form of the probability transitions of the chain $(X_n)$ it is easy to see that this chain is aperiodic, recurrent and ergodic. Furthermore, its unique invariant and reversible probability measure is given by

$$\pi(dx) = \frac{2^{2/3}\sqrt{\pi}}{\Gamma(1/3)\Gamma(1/6)} \frac{e^x}{(e^x - 1)^{2/3}}.$$

An application of the ergodic theorem implies that $n^{-1} \log \xi(n) = n^{-1}(X_0 + X_1 + \cdots + X_{n-1})$ converges almost surely and in $L^1$ towards\footnote{Here and later, unexplained integrations have been realized using Mathematica©}

$$\int_{\mathbb{R}^+} \pi(dx)x = \frac{\pi}{\sqrt{3}},$$

which is the constant appearing in the statement of the Proposition 8.
We now setup large deviations estimates. Recall that a set \( C \subset \mathbb{R}_+ \) is small \([34, \text{p} 102]\) if there exists a probability measure \( \nu \) and \( \varepsilon > 0 \) such that for some \( k \geq 1 \) the \( k \)-steps transition kernel satisfies

\[
p^k(x, A) \geq \varepsilon \nu(A), \quad \forall x \in C, \quad \forall A \text{ Borel}.
\]

This will allow us to apply the powerful machinery developed in \([34, \text{Chapter 16}]\). For this, we compute the variation of \( V \) after applying a one step transition of the chain:

\[
pV(x) := \int p(x, dy) V(y) = \frac{\sqrt{3}}{2\pi} \left( \frac{e^x - 1}{e^x} \right)^{1/3} \int_0^\infty \frac{dy}{(ey - 1)^{1/3} - e^{-x-y}}.
\]

It is easy to see that \( pV(x) \leq K \) for some constant \( K > 0 \) uniformly in \( x \geq 1 \). On the other hand, when \( x \to 0 \) we have

\[
pV(x) \sim \frac{\sqrt{3}}{2\pi} x^{1/3} \int_0^\infty \frac{dy}{y^{1/3}(x+y)} = x^{-1/4} \cdot \frac{\sqrt{3}}{2\pi} \int_0^\infty \frac{dz}{z^{7/12}(1+z)}
\]

where we have performed the change of variable \( y = xz \). The right-hand side can be computed exactly and is equal to \( V(x) \cdot \frac{\sqrt{3}}{1 + \sqrt{3}} \) for \( x < 1 \). Since \( \frac{\sqrt{3}}{1 + \sqrt{3}} < 1 \) we deduce that the condition \((V4)\) of \([34, \text{p} 376]\) is indeed satisfied and thus the chain is \( V \)-geometrically ergodic.

We first establish upper large deviations for the partial sums of the \( X_i \). Fix \( \eta > 0 \) and find \( a \geq 0 \) such that

\[
\int_a^\infty \frac{dy}{(1 - e^{-y})(ey - 1)^{1/3}} \leq \frac{\eta}{10}, \quad (34)
\]

We have

\[
P \left( n^{-1} \sum_{i=0}^{n-1} X_i - \frac{\pi}{\sqrt{3}} > \eta \right) \leq P \left( n^{-1} \sum_{i=0}^{n-1} X_i 1_{X_i \geq a} > \eta/2 \right) + P \left( n^{-1} \sum_{i=0}^{n-1} X_i 1_{X_i < a} - \frac{\pi}{\sqrt{3}} > \eta/2 \right). \quad (35)
\]

Note that \( F : x \mapsto x 1_{x < a} \) is a bounded function, so we can apply the results of \([25]\) and get that

\[
\lim_{n \to \infty} \mathbb{D} \left( \sum_{i=0}^n F(X_i), n \right) = \mathbb{E}_\pi[F(X)].
\]

In particular since \( \mathbb{E}_\pi[F(X)] \leq \mathbb{E}_\pi[X] = \pi/\sqrt{3} \) we deduce that for some \( c_1, c_2 > 0 \) we have

\[
P \left( n^{-1} \sum_{i=0}^{n-1} X_i 1_{X_i < a} > \eta/2 + \frac{\pi}{\sqrt{3}} \right) \leq c_1 e^{-c_2 n}.
\]

To control the other term of the right-hand side of \((35)\), we remark that the probability transitions of the chain \((X)\) are bounded from above by

\[
p(x, dy) \leq \frac{dy}{(1 - e^{-y})(ey - 1)^{1/3}}.
\]

32
And so
\[
P \left( n^{-1} \sum_{i=0}^{n-1} X_i 1_{X_i \geq a} > \eta/2 \right) \leq P \left( n^{-1} \sum_{i=0}^{n-1} Z_i > \eta/2 \right),
\]
where \((Z_i)\) are i.i.d. random variables of law given by
\[
1_{y > a} \frac{dy}{(1 - e^{-y})(e^y - 1)^{1/3}} + \left( 1 - \int_a^\infty \frac{dx}{(1 - e^{-x})(e^x - 1)^{1/3}} \right) \delta_0.
\]

Since \(Z_i\) has mean less than \(\eta/10\) by (34) and has exponential moments, large deviations estimates (28) show that the last term is bounded by \(c_1 e^{-c_2 n}\) for some \(c_1, c_2 > 0\). This completes the upper large deviations for the partial sums of the chain \(X\), the lower large deviations are similar and left to the reader.

As a corollary of the last proposition, we study the number of alternative minimal records of two independent stable processes \((S^+, S^-)\) between the times when \(S^+_i\) is between two fixed values. More precisely, for any \(x > 0\) set \(\vartheta_x = \inf \{t \geq 0 : S^+_i \leq -x\}\) and for \(0 < x < y\) put
\[
\operatorname{ComStable}(x, y) = \inf \left\{ k \in \{1, 3, 5, \ldots \} : \xi^{(k)}(\vartheta_x) \geq \vartheta_y \right\}.
\]
Remark that by scale invariance of the stable processes we have \(\operatorname{ComStable}(x, y) = \operatorname{ComStable}(1, y/x)\) in distribution.

**Corollary 11.** We have \(\lim_{x \to \infty} \text{LD}(\operatorname{ComStable}(1, x), \log x) = \frac{3\sqrt{3}}{2\pi}\).

**Proof.** By monotonicity of \(t \mapsto \xi^{(k)}(t)\) and of \(k \mapsto \xi^{(k)}(t)\), note that if \([b \log x]\) is odd and if we have simultaneously \(\vartheta_x \leq x^a, \vartheta_1 \geq x^{-\varepsilon}\) and \(\xi^{[b \log x]}(x^{-\varepsilon}) \geq x^a\) then we have \(\operatorname{ComStable}(1, x) \leq [b \log x]\). Taking \(\frac{\pi}{\sqrt{3}} b > (a + \varepsilon) > a > 3/2\) and using the last proposition together with (29) we get that for large \(x\) so that \([b \log x]\) is odd
\[
P(\operatorname{ComStable}(1, x) > [b \log x])
\leq \sum_{a} P(\xi^{[b \log x]}(x^{-\varepsilon}) \leq x^a) + P(\vartheta_x \leq x^a) + P(\vartheta_1 \leq x^{-\varepsilon})
\leq \sum_{a} P(\xi^{[b \log x]}(x^{-\varepsilon}) \leq x^a) + P(S^+_{x^a} \geq -x) + P(S^-_{x^{-\varepsilon}} \leq -1)
\leq \sum_{a} P \left( \frac{\log \xi^{[b \log x]}}{\log x} \leq (a + \varepsilon) \right) + P(S^+_{x^a} \geq -x^{1-2\varepsilon}/3) + P(S^+_{x^{-\varepsilon}} \leq -x^{2\varepsilon}/3)
\leq c_1 e^{-c_2 \log x}
\]
for some \(c_1, c_2 > 0\) (depending on the parameters). This thus holds for any \(b > \frac{3\sqrt{3}}{2\pi}\). The other inequality is similar. This proves the corollary.

**3.3 An SLE_{\theta} calculation: estimates for \(\theta^{(n)}\)**

In order to lighten notation, in this section we put \(\theta^{(n)} := \theta^{(n)}(1)\).

**Proposition 12.** We have \(\lim_{n \to \infty} \left( \log \theta^{(n)}, n \right) = \frac{4\pi}{\sqrt{3}}\).
\textbf{Proof.} Recall the notation of Section 2.3. We start by a few classical facts on the SLE processes, see e.g. [26, Section 8.3] for details. The image of the boundary of the hull $\mathbb{H} \setminus H_x$ inside $\mathbb{H}$ is sent by the uniformization mapping $g_t$ to a segment $[L_t, R_t]$ and $g_t(\gamma_t)$, denoted by $U_t$, lies inside $[L_t, R_t]$. In particular, the times when $\gamma$ touches $\mathbb{R}_+$ correspond to the times when $U_t = R_t$ and similarly for the left part. That is $\theta^{(0)} = 1$ and $\theta^{(i+1)} = \inf\{t \geq \theta^{(i)} : U_t = R_t\}$ for $i$ even and $\theta^{(i+1)} = \inf\{t \geq \theta^{(i)} : U_t = L_t\}$ for $i$ odd. We now derive the equations driving these processes, we refer to [26, Section 8.3] for more details. The Loewner equation (16) tells us that
\[ dU_t = \sqrt{6} dB_t, \]
where $B$ is a standard Brownian motion. Also an easy calculation using (16) shows that as long as $U_t \neq R_t$ and $U_t \neq L_t$ we have
\[ dL_t = \frac{2 dt}{L_t - U_t}, \quad \text{and} \quad dR_t = \frac{2 dt}{R_t - U_t}. \]
However, since the parameter of the SLE is $\kappa = 6$, we will have infinitely many times at which $L_t = U_t$ or $R_t = U_t$ and the meaning of the last display is not clear anymore. One way to cope-up with this to first define simultaneously the processes $G_t = (U_t - L_t)^2$ and $D_t = (R_t - U_t)^2$ as the solutions of
\[ dG_t = 2 \sqrt{G_t} dU_t + 10 dt \quad \text{and} \quad dD_t = -2 \sqrt{D_t} dU_t + 10 dt, \]
starting from $0$ (with the same Brownian motion). Consequently, both $G_t$ and $D_t$ are distributed as $1/6$ times a squared Bessel process of dimension $5/3$ and are defined for all $t \geq 0$, see [37, Chap. XI]. From the triplet $(G_t, U_t, D_t)$ we can then construct $(L_t, U_t, R_t) = (U_t - \sqrt{G_t}, U_t, \sqrt{D_t} - U_t)$ for all times $t \geq 0$, see [26, Chapter 8.3]. If we put
\[ X_t = \frac{U_t - L_t}{R_t - L_t}, \]
and $\Delta_t = R_t - L_t$ applying Ito’s formula we get
\[ dX_t = \frac{dU_t}{\Delta_t} + \frac{2 dt}{\Delta_t^2} \left( \frac{1}{X_t} - \frac{1}{1 - X_t} \right), \]
which can be defined for all $t \geq 0$ using the above device. Performing the following time-change
\[ r(t) = \int_{1}^{t} \frac{ds}{\Delta_s}, \quad Z_{r(t)} = X_t \]
we obtain that $Z$ satisfies
\[
\begin{cases}
Z_0 & = X_1 \\
\frac{dZ_t}{Z_t} & = \frac{dU_t}{Z_t} + 2 dt \left( \frac{1}{Z_t} - \frac{1}{1 - Z_t} \right).
\end{cases}
\]
Using $r$, the $\theta^{(i)}$ can be recovered from the alternative hitting times $r(\theta^{(i)})$ of $1$ and $0$ by the process $Z$. We now have two tasks. Firstly, understand the number of commutings between $0$ and $1$ for the process $Z$ as time goes to infinity, and secondly understand the asymptotics of the time change $r(t)$ in order to translate these results back to the $\theta^{(i)}$.

\textbf{Commutings of $Z$.} The process $Z$ is strong Markov and symmetric with respect to $1/2$. By looking at the SDE governing $Z$ we see that it evolves like a Bessel of dimension $5/3$ around $0$ and symmetrically around $1$. In particular, starting from $0$ the process $Z$ will eventually hit $1$ in finite time a.s. and vice versa. For $x \in [0, 1]$, under $E_x$ the process $Z$ starts from $x$. We let $t_0$ and $t_1$ be the hitting times of $0$ and $1$ respectively by the process $Z$. We now state a technical lemma:
Lemma 13. For some \( \lambda > 0 \) we have
\[
E_0 \left[ \exp \left( \lambda \int_0^{t_1} \frac{du}{Z_u(1 - Z_u)} \right) \right] < \infty.
\]
In particular \( E_0[\exp(\lambda t_1)] < \infty \). Furthermore we have
\[
E_0[t_1] = E_1[t_0] = \frac{\pi}{7\sqrt{3}}.
\]

Proof of Lemma 13. By symmetry in space and time of the process \( Z \), to prove the first assertion of the lemma, it is sufficient to prove that for some \( \lambda > 0 \) we have
\[
E_{1/2} \left[ \exp \left( \lambda \int_0^{t_0 \wedge t_1} \frac{du}{Z_u(1 - Z_u)} \right) \right] < \infty.
\] (37)

For this we introduce the scale function \( \phi \) of the process \( Z \) which is defined for \( x \in [0, 1] \) by
\[
\phi(x) = \int_0^x \frac{du}{u(1 - u)}^{2/3}.
\]
In particular we have \( \Lambda := \phi(1) = \frac{\Gamma(1/6)\Gamma(1/3)}{2^{2/3}\sqrt{\pi}} \) and \( \phi \) satisfies 2\phi'(x)(\frac{1}{x} - \frac{1}{1-x}) + 3\phi''(x) = 0. \) Applying Ito’s formula, it comes as no surprise that \( Y_1 = \phi(Z_{t \wedge t_0 \wedge t_1}) \) is a local martingale under \( E_{1/2} \). Since the later is bounded it is even a true martingale. By the Dubins-Schwarz theorem, \( Y \) is a time change of a Brownian motion. Specifically, we can write \( Y_t = \beta_{<Y>_t} \) where \( \beta \) is a standard Brownian motion started from \( \Lambda/2 \). Stochastic calculus shows that \( d<Y>_u = 6(\phi' \circ \phi^{-1})^2(\beta_{<Y>_u})du \), consequently after the change of variable \( v = <Y>_u \) we have
\[
\int_0^{t_0 \wedge t_1} \frac{du}{Z_u(1 - Z_u)} = \int_0^{t_0 \wedge t_1} \frac{du}{\phi^{-1}(\beta_{<Y>_u})(1 - \phi^{-1}(\beta_{<Y>_u}))} = \int_{\tau_0 \wedge \tau_\Lambda}^{\tau_0 \wedge \tau_\Lambda} \frac{dv}{6(\phi' \circ \phi^{-1})^2 \cdot \phi^{-1}(1 - \phi^{-1})(\beta_v)} = \int_{\tau_0 \wedge \tau_\Lambda}^{\tau_0 \wedge \tau_\Lambda} dv \psi \circ \phi^{-1}(\beta_v)
\]
where \( \psi : x \mapsto 6(x(1-x))^{1/3} \) and \( \beta \) is a Brownian motion started from \( \Lambda/2 \) and stopped at \( \tau_0 \wedge \tau_\Lambda \), the first hitting time of 0 or of \( \Lambda \) by \( \beta \). Since the function \( \psi \) is bounded by 6 over \([0, 1]\) we deduce that
\[
\int_0^{t_0 \wedge t_1} \frac{du}{Z_u(1 - Z_u)} \leq 6 \cdot \tau_0 \wedge \tau_\Lambda.
\]
It is classical that \( \tau_0 \wedge \tau_\Lambda \) has some exponential moment and so (37) follows.

We easily deduce from the first point that under \( E_0 \) the variable \( t_1 \) possesses some exponential moments and is in particular integrable. To compute its expectation consider now the function \( f : [0, 1] \rightarrow \mathbb{R} \) which is \( C^2 \) over \([0, 1]\), with \( f(0) = 0, f'(0) = 0 \) and which satisfies the differential equation
\[
2f'(x)\left(\frac{1}{x} - \frac{1}{1-x}\right) + 3f''(x) = 1.
\]
Such a function exists and can be expressed using hypergeometric functions\(^6\). This function is positive, continuous over \([0, 1]\) and \( f(1) - f(0) = \frac{\pi}{7\sqrt{3}} \). Another application of Ito’s formula shows that
\[
(f(Z_t) - t)_{t < t_1}
\]

\(^6\) A computation with Mathematica gives \( f(x) = 1/14(-x + x^2 + x\text{HypergeometricPFQ}[[1, 1, 4/3], [5/3, 2], x]) \)
is a local martingale. Since $f$ is bounded it is even a true martingale. Applying the optional sampling theorem we deduce that $E_0[f(Z_{t \wedge t_1})] = E_0[t_1 \wedge t]$ for every $t \geq 0$. Letting $t \to \infty$ we get by the dominated and monotone convergences theorems that
\[ E_0[t_1] = f(1) - f(0) = \frac{\pi}{7\sqrt{3}}. \quad \square \]

Let us now come back to the proof of Proposition 12. By applying the strong Markov property at the successive and alternate hitting times of 1 and 0 by the process $Z$, we deduce that the $n$th interlaced hitting time $r(\theta^{(n)})$ of $\{0, 1\}$ by the process $Z$ is given by $r(\theta^{(1)}) + t^{(2)} + \cdots + t^{(n)}$ where $t^{(i)}$ are i.i.d. copies of $t_1$ under $E_0$. We deduce from Lemma 13 and (28) that
\[ \lim_{n \to \infty} \left( r(\theta^{(n)}), \frac{n}{r} \right) = \frac{\pi}{7\sqrt{3}} \] (38)

\textbf{ASYMPTOTICS OF THE TIME-CHANGE.} We now prove that
\[ \lim_{t \to \infty} \log(t) \log(t) = \frac{1}{28} \] (39)
which will together with the last display imply the proposition. Indeed, by monotonicity of $t \mapsto r(t)$ and $k \mapsto \theta^{(k)}$, if for some number $c \geq 0$ we have both $r(\theta^{(n)}) \geq c$ and $r(t) \leq c$ then $\theta^{(n)} \geq t$. Choosing $\frac{\pi}{7\sqrt{3}} > a$ and $b = \frac{1}{28}$ and setting $c = b \log t = an$ we have
\[ P\left( \theta^{(n)} < t \right) = P\left( \frac{\log \theta^{(n)}}{n} < \frac{a}{b} \right) \leq P\left( \frac{r(\theta^{(n)})}{n} \leq an \right) + P\left( r(t) \leq b \log t \right) \]
\[ \leq \frac{c_1 \exp(-c_2n)}{4\pi} \] (38) and (39)
for some constants $c_1, c_2 > 0$. Since $a/b$ can be made arbitrarily close to $4\pi/\sqrt{3}$ this proves one side of the proposition, the other inequality is similar.

From the SDE satisfied by $\Delta_s$ we get that
\[ d\Delta_s = \frac{2ds}{\Delta_s X_s(1 - X_s)} \]
\[ d(\log \Delta_s) = \frac{ds}{2 \Delta_s^2 X_s(1 - X_s)}. \]
Integrating over $[1, t]$ and performing the change of variable $u = r(t)$ with $du = dt/\Delta_t^2$ we get
\[ \log(\Delta_t) - \log(\Delta_1) = \int_0^{r(t)} \frac{2du}{Z_u(1 - Z_u)}. \] (40)
Recall that $\Delta_t = R_t - L_t$ is the sum of two (depend) multiples of Bessel processes of dimension 5/3. The scaling property of these then imply that $\Delta_t = \sqrt{t} \Delta_1$ in distribution and easy estimates actually show that
\[ \lim_{t \to \infty} \log(\Delta_t, \log t) = \frac{1}{2}. \] (41)
On the other hand, recall that the invariant measure of a diffusion $dZ_t = -\nabla \psi(t)dt + \sqrt{2\beta^{-1}}dB_t$ is proportional to $\rho(dx) \propto \exp(-\beta \psi(x))dx$. In the case of $Z$, the invariant probability measure is thus
\[ \rho(dx) = \frac{\Gamma(10/3)}{\Gamma(5/3)^2} (x(1-x))^{2/3}. \]
In particular an application of the ergodic theorem shows that

$$\lim_{t \to \infty} t^{-1} \int_0^t \frac{du}{Z_u(1 - Z_u)} = \int_0^1 \frac{\rho(dx)}{x(1 - x)} = 7,$$

almost surely and in $L^1$. We can strengthen the last display. Indeed, by decomposing the process $Z$ into independent excursions between 0 and 1, and using Lemma 13 and (28) one deduces that large deviations hold for the last display, that is

$$\lim_{t \to \infty} \text{LD} \left( \int_0^t \frac{du}{Z_u(1 - Z_u)}, t \right) = 7.$$

It is now easy to combine the last display with (41) and (40) to complete the proof of (39). □

As a corollary of the last proposition, we study the number of alternative bouncings on $\mathbb{R}_+$ and $\mathbb{R}_-$ that the curve $\gamma$ is doing between two fixed points. Recall the notation introduced before (30). For any $x > 0$, set $\varkappa_x = \inf\{t \geq 0 : \gamma_t^+ \geq x\}$ and for $0 < x < y$ put

$$\text{ComSLE}(x, y) = \inf\{k \in \{1, 3, 5, \ldots\} : \theta(\varkappa_x) \geq \varkappa_y\}.$$

Remark that by scale invariance of the stable processes we have $\text{ComSLE}(x, y) = \text{ComSLE}(1, y/x)$ in distribution.

**Corollary 14.** We have $\lim_{x \to \infty} \text{LD} \left( \text{ComSLE}(1, x), \log x \right) = \frac{\sqrt{3}}{2\pi}.$

**Proof.** The proof is similar to that of Corollary 11 and follows from the last proposition together with the square-root scaling property of the SLE$_6$ process. Let us repeat the argument. By monotonicity of $t \mapsto \theta(\varkappa)(t)$ and of $k \mapsto \theta(\varkappa)(t)$, note that if $[b \log x]$ is odd and if we have simultaneously $\varkappa_x \leq x^a$, $\varkappa_1 \geq x^{-\varepsilon}$ and $\theta([b \log x])(x^{-\varepsilon}) \geq x^a$ then we have $\text{ComSLE}(1, x) \leq [b \log x]$. Taking $\frac{4\pi}{\sqrt{3}} b > (a + \varepsilon) > a > 2$ and using the last proposition together with (30) we get that for large $x$ so that $[b \log x]$ is odd

$$P(\text{ComSLE}(1, x) > [b \log x]) \leq P(\theta([b \log x])(x^{-\varepsilon}) \leq x^a) + P(\varkappa_x \geq x^a) + P(\varkappa_1 \leq x^{-\varepsilon}) = P(x^\varepsilon \cdot \theta([b \log x])(x^{-\varepsilon}) \leq x^{a+\varepsilon}) + P(\gamma_1^+ \leq x) + P(\gamma_1^+ \geq x^{-\varepsilon}) \leq \text{scaling} \left( \frac{\log \theta([b \log x])}{\log x} \leq (a + \varepsilon) \right) + P(\gamma_1^+ \leq x^{1-a/2}) + P(\gamma_1^+ \geq x^{\varepsilon/2}) \leq \text{Prop. 12 and (30)}$$

for some $c_1, c_2 > 0$ (depending on the parameters). This thus holds for any $b > \frac{\sqrt{3}}{2\pi}$. The other inequality is similar. This proves the corollary. □

**Remark 4.** These commuting estimates for the SLE$_6$ might also alternatively be obtained using the work of Hongler and Smirnov [20]. Indeed, these authors computed the limit of the expected number of clusters for critical site percolation in a rectangle as the mesh goes to 0. In terms of the percolation interface, this boils down to compute the expectation of the number of commutings the latter is doing between the top and bottom boundaries of the rectangle. Since the limit of the
percolation interface is the SLE$_6$ curve, by conformal invariance these calculations can be translated into the expected number of times an SLE$_6$ bounces off $\mathbb{R}_+$ and $\mathbb{R}_-$ in a semi-ring region, see Fig. 19. We preferred not to take this approach (which would require additional work to get large deviations estimates) and rather stayed on the continuous setup.

4 Conformal measure on the boundary

With all the ingredients that we have developed we can now proceed to the proof of Theorem* 1. Consider the uniformization of a UIHPT onto $\mathbb{H}$ such that the origin and target of the root edge are sent to $-\frac{1}{2}$ and $\frac{1}{2}$ and $\infty$ to $\infty$. Recall also that the $k$th vertex on the right of the origin of $T_{\infty,\infty}$ has image $X_k \in \mathbb{R}_+$. The sketch of the proof of Theorem* 1 $(iii)$ can be found in the introduction, however the following lines are a bit more technical since we will need precise estimates to rigorously derive the Hausdorff dimension of $\mu$.

4.1 Discrete estimates

Proposition* 4. Let $\eta, \varepsilon \in (0, 1)$. Then there exist $c_1, c_2 > 0$ such that

$$\limsup_{n \to \infty} P \left( \left| \log \frac{X_{\lceil \varepsilon n \rceil}}{X_n} - 3 \log \varepsilon \right| > \eta | \log \varepsilon | \right) \leq c_1 \exp(-c_2 | \log \varepsilon |).$$

Proof. Fix $\varepsilon \in (0, 1)$. Denote by $t_{\varepsilon,n}$ the first time the exploration process triggers a peeling step that “swallows” or touches the $\lceil \varepsilon n \rceil$th vertex on the right of the root edge, recalling (11) we thus have

$$t_{\varepsilon,n} = \inf \{ k \geq 0 : \mathcal{H}^+(k) \leq -[\varepsilon n] \}. $$

(Note that this time is almost surely finite by Theorem* 2.) Introduce then the number of discrete remaining commutings necessary to discover the $n$th point on the right boundary, that is

$$C_{\text{dis}}(\varepsilon, n) = \inf \{ k \in \{1, 3, 5, \ldots \} : \mathcal{H}^+ \left( \tau^{(k)}(t_{\varepsilon,n}) \right) \leq -n \}. $$

By Theorem* 2 and using standard arguments as those developed in Section 3.1, the random variable $C_{\text{dis}}(\varepsilon, n)$ converges in distribution as $n \to \infty$ towards the random variable $\text{ComStable}(\varepsilon, 1)$ defined just before Corollary 11. The same Corollary 11 thus entails that for every $\eta > 0$ there exist $c_1, c_2 > 0$ such that

$$\limsup_{n \to \infty} P \left( \left| \frac{\log C_{\text{dis}}(\varepsilon, n)}{| \log \varepsilon |} - \frac{3\sqrt{3}}{2\pi} \right| > \eta \right) \leq c_1 \exp(-c_2 | \log \varepsilon |).$$

(42)
Let us now focus on the SLE exploration. An easy adaptation of Proposition* 3 implies that the number $C^{\text{dis}}(\varepsilon, n)$ is asymptotically equal as $n \to \infty$ to the number of commutings the SLE$_6$ is doing after having swallowed the point $X_{[\varepsilon n]}$ until it swallows $X_n$, i.e.,

$$|C^{\text{dis}}(\varepsilon, n) - \text{ComSLE}(X_{[\varepsilon n]}, X_n)| \xrightarrow{(P)}_{n \to \infty} 0.$$  

Consequently, by the last display and (42) we have

$$\limsup_{n \to \infty} P \left( \left| \log \frac{\text{ComSLE}(X_{[\varepsilon n]}, X_n)}{\log \varepsilon} - \frac{3\sqrt{3}}{2\pi} \right| > \eta \right) \leq c_1 \exp(-c_2 |\log \varepsilon|). \tag{43}$$

Since the SLE$_6$ is independent of the map, if we condition on $\mathcal{T}_{X_{[\varepsilon n]}, X_n}$, using Corollary 14 we get that for small enough $\varepsilon > 0$ we have (note that $4 \cdot \frac{\sqrt{3}}{2\pi} > 1$)

$$P \left( \left| \log \frac{\text{ComSLE}(X_{[\varepsilon n]}, X_n)}{\log \varepsilon} - \frac{3\sqrt{3}}{2\pi} \right| > \eta \left( \left| \log \frac{X_{[\varepsilon n]}}{X_n} - 3\log \varepsilon \right| > 4\eta |\log \varepsilon| \right) \right) \geq \frac{1}{2}. \tag{44}$$

So that for small enough $\varepsilon > 0$:

$$\limsup_{n \to \infty} P \left( \left| \log \frac{X_{[\varepsilon n]}}{X_n} - 3\log \varepsilon \right| > 4\eta |\log \varepsilon| \right) \leq \frac{1}{2}$$

$$\leq \limsup_{n \to \infty} P \left( \left| \log \frac{\text{ComSLE}(X_{[\varepsilon n]}, X_n)}{\log \varepsilon} - \frac{3\sqrt{3}}{2\pi} \right| > \eta \right)$$

$$\leq c_1 \exp(-c_2 |\log \varepsilon|).$$

This completes the proof of the proposition*.

We will also rely on an adaptation of the last proposition* in order to compare the relative positions of $X_k$ and $X_{k'}$ when $k$ and $k'$ are of the same order.

**Proposition* 5.** For every $u > 0$ and for every $\eta > 0$, there exist $c_1, c_2 > 0$ such that we have

$$\limsup_{n \to \infty} P \left( \left| \log \frac{X_{[un]}}{X_n} \right| \geq \eta |\log \varepsilon| \right) \leq c_1 e^{-c_2 |\log \varepsilon|}. \tag{45}$$

**Sketch of the proof.** The proof uses the same arguments as in Proposition* 4 so we only sketch it. Fix $u < 1$ for definiteness and consider $C^{\text{dis}}(u, n)$ to be the number of commutings realized by the horodistance process between the discovery of the $[un]$th vertex on the right of $\mathbf{e}$ and the $n$th one. On the one hand, as in Proposition* 4, $C^{\text{dis}}(u, n)$ converges as $n \to \infty$ towards $\text{ComStable}(u, 1)$ which is of order 1. On the other hand, using the SLE$_6$ interpretation of the exploration (and Proposition* 3) we also get that $C^{\text{dis}}(u, n) - \text{ComSLE}(X_{[un]}, X_n)$ converges towards 0 in probability as $n \to \infty$. Using Corollary 11 and 14 we thus get that

$$1 \approx \text{ComStable}(u, 1) \approx \text{ComSLE}(X_{[un]}, X_n) \approx \frac{\sqrt{3}}{2\pi} \log \frac{X_n}{X_{[un]}},$$

so that $X_{[un]}$ and $X_n$ are of the same order of magnitude. Details are left to the reader.

We extend the definition of $X_k$ to every integer $k \in \mathbb{Z}$ in a straightforward manner.
**Proposition 15** (Re-rooting and symmetry). For every \( n \geq 0 \) and every integer \( u_n \) we have the following identity in distribution

\[
\left( \frac{X_{k+u_n} - X_{u_n}}{X_{n+u_n} - X_{u_n}} \right)_{k \geq 0} \overset{(d)}{=} \left( \frac{X_k}{X_n} \right)_{k \geq 0} \overset{(d)}{=} \left( \frac{X_k - u_n}{X_n} \right)_{k \geq 0}.
\]

**Proof.** For \( n \geq 0 \), the lattice \( \tilde{T}_{\infty, \infty} \) obtained from \( T_{\infty, \infty} \) after re-rooting at the \( u_n \)th edge on the right of \( \vec{e} \) is still distributed as the UIHPT. The uniformization \( \tilde{T}_{\infty, \infty} \) of \( T_{\infty, \infty} \) (with the root edge sent to \([-1/2, 1/2]\) and infinity to infinity) is obtained from \( T_{\infty, \infty} \) by translation and dilation. Thus if \( (\tilde{X}_k) \) denotes the positions of the vertices on the right of the root edge of the uniformization of \( \tilde{T}_{\infty, \infty} \) we get that

\[
\left( \frac{X_{k+u_n} - X_{u_n}}{X_{n+u_n} - X_{u_n}} \right)_{k \geq 0} = \left( \frac{\tilde{X}_k}{\tilde{X}_n} \right)_{k \geq 0}.
\]

Since \( (\tilde{X}_k)_{k \geq 0} \) has the same law as \( (X_k)_{k \geq 0} \) the first identity in distribution follows. The second one is obtained by flipping \( T_{\infty, \infty} \) horizontally, operation which leaves its distribution unchanged. \( \square \)

Combining Proposition* 5 with Proposition 15 we deduce that

\[
\limsup_{n \to \infty} P\left( \star \geq \eta | \log \varepsilon | \right) \leq c_1 e^{-c_2 | \log \varepsilon |}
\]

where \( \star \) can be replaced by

\[
\star = \frac{X_{[n/2]} - X_n}{X_n} \text{ or } \frac{X_n - X_{[n/2]}}{X_n} \text{ or } \frac{X_{[3n/2]} - X_n}{X_n} \text{ or } \frac{X_{[3n/2]} - X_{[n/2]}}{X_n}.
\]

After some manipulations this eventually implies

\[
\limsup_{n \to \infty} P\left( \left| \log \left( \frac{X_{[3n/2]} - X_n}{X_n} \right) \land \left( \frac{X_n - X_{[n/2]}}{X_n} \right) \right| \geq \eta | \log \varepsilon | \right) \leq c_1 e^{-c_2 | \log \varepsilon |}, \tag{45}
\]

### 4.2 Dimension of the random measure

Recall that we consider the random measure \( \mu_n \) defined by

\[
\mu_n = \frac{1}{n} \sum_{k=1}^{n} \delta_{X_k/X_n}.
\]

Hence \( \mu_n \) is a random probability measure on \([0, 1]\). We briefly remind the reader about the basics of convergence in distribution for random measures on \( \mathbb{R} \) (the interested should consult the authoritative reference [23] for proofs and more general statements and [19] for a smooth introduction). We endow the set \( \mathcal{M} \) of all positive Radon measures on \( \mathbb{R} \) with the topology \( \mathcal{T} \) of vague convergence, that is, the weakest topology which makes the mappings

\[ \mu \in \mathcal{M} \mapsto \mu f := \int_{\mathbb{R}} df, \quad f \in C_K, \]

continuous. (Here, \( C_K \) is the set of continuous functions \( f : \mathbb{R} \to \mathbb{R} \) with compact support.) A random measure is a random element of the space \( (\mathcal{M}, \mathcal{T}) \), viewed as a measurable space with \( \sigma \)-algebra generated by the sets in \( \mathcal{T} \). A sequence \( \lambda_1, \lambda_2, \ldots \) of random measures converges in
To get the third part of Theorem 1 we will prove that balls of radius $r$.

Corollary 6

The following result (see for example [32, Lemma 4.1]):

roughly have volume $r$.

Additionally on Conditionally on $\mu$

Proof.

By definition of $\mu$, let $X_n$ be a random point sampled accord to $\mu_n$ and similarly conditionally on $\mu$, let $X$ be sampled according to $\mu$. By definition of $\mu_n$ notice that we can write $X_n = X_{[Un]} / X_n$ where $U \in (0, 1)$ is a uniform random variable independent of $T_{\infty, \infty}$ and $[a]$ is the lowest integer larger than $a$. Now fix $a < 1/3$ and write $x = r^a$. Since $\mu$ is the (subsequential limit) of the $\mu_n$'s we have

$$P(\mu_{B_r(X)} \geq 8x) \leq \limsup_{n \to \infty} P(\mu_{B_r(X_n)} \geq 4x) \leq \limsup_{n \to \infty} P(\mu_n[X_n, X_n + r] \geq 2x) + \limsup_{n \to \infty} P(\mu_n[X_n - r, X_n] \geq 2x).$$

By definition of $\mu_n$, note that the event $\{\mu_n[X_n, X_n + r] \geq 2x\}$ can be written as

$$\{\mu_n[X_n, X_n + r] \geq 2x\} = \left\{ \frac{X_{[Un]} + [2xn] - 1 - X_{[Un]}}{X_n} \leq r \right\} \subset \text{large } n's \left\{ \frac{X_{[xn] + [Un]} - X_{[Un]}}{X_n} \leq r \right\}.$$

We now write

$$P \left( \frac{X_{[xn]} + [Un] - X_{[Un]}}{X_n} \leq r \right) = P \left( \frac{X_{[xn]} + [Un] - X_{[Un]}}{X_{n+[Un]} - X_{[Un]}} \cdot \frac{X_{n+[Un]} - X_{[Un]}}{X_n} \leq r \right) \leq P \left( \log \frac{X_{[xn]} + [Un] - X_{[Un]}}{X_{n+[Un]} - X_{[Un]}} \leq (1 - \varepsilon) \log r \right) + P \left( \log \frac{X_{n+[Un]} - X_{[Un]}}{X_n} \leq \varepsilon \log r \right) \leq P \left( \log \frac{X_{[xn]} + u_n - X_{[xn]}}{X_{n+u_n} - X_{u_n}} \leq (1 - \varepsilon) \log r \right) + P \left( \log \frac{(X_{[3n/2]} - X_{n}) \wedge (X_n - X_{[n/2]})}{X_n} \leq \varepsilon \log r \right),$$
where we have chosen \( \varepsilon > 0 \) so that \( (1 - \varepsilon)/a > 3 \) and put \( u_n = \lfloor Un \rfloor \). Indeed notice that when \( U \in (0, 1) \) then \( \lfloor Un + \lfloor Un \rfloor \rfloor \) contains either \( \lfloor n/2 \rfloor \) or \( \lfloor 3n/2 \rfloor \). We can take \( \limsup \) and apply Proposition 15 together with Proposition* 4 to the first member of the right-hand side and (45) to the second member of the right-hand side to deduce that there exist constants \( c_1, c_2 > 0 \) so that

\[
\limsup_{n \to \infty} P (\mu_n [X_n, X_n + r] \geq 2x) \leq c_1 \exp(-c_2|\log r|).
\]

A similar reasoning holds for \( \limsup_{n \to \infty} P (\mu_n [X_n - r, X_n] \geq 2x) \). Gather-up the pieces of (46) and establishing the corresponding lower bound (left to the reader) we finally get that

\[
\lim_{r \to 0} \text{LD} (\log \mu B_r(X), \log r) = \frac{1}{3}.
\]

Taking \( r = 2^{-k} \), the Borel–Cantelli lemma shows that \( \frac{\log \mu B_{2^{-k}}(X)}{\log 2^{-k}} \to \frac{1}{3} \) almost surely as \( k \to \infty \) which easily implies the statement of the corollary*.

\[\square\]

**Corollary* 7.** The random probability measure \( \mu \) is almost surely non-atomic.

**Proof.** This is a straightforward consequence of the last corollary*. Indeed, if \( \mu \) had a probability at least \( \varepsilon > 0 \) of having an atom of mass at least \( \varepsilon \) then \( X \) would be located on a point of \( \mu \)-mass \( \varepsilon \) with probability at least \( \varepsilon^2 \) and Corollary* 6 would not hold.

\[\square\]

### 4.3 Full support

**Proposition* 8.** The random probability measure \( \mu \) has topological support equal to \([0, 1]\) a.s.

**Proof.** Let us argue by contradiction and suppose that with positive probability \( \mu \) has not full support i.e. \( P(\exists x \in [0, 1] \text{ and } \varepsilon > 0 : \mu B_\varepsilon(x) = 0) > 0 \). By compactness, we can thus suppose that for some some \( x \in [0, 1] \) and \( \varepsilon \in (0, 1) \) we have \( P(\mu B_{2\varepsilon}(x) = 0) \geq 2\varepsilon \). We will further assume that \( x > 2\varepsilon \) and

\[
P(\mu B_{2\varepsilon}(x) = 0 \text{ and } \mu B_{\varepsilon/2}(0) \geq 2\varepsilon) \geq 2\varepsilon.
\]

(The boundary case \( x = 0 \) is similar and left to the reader). Going back to a discrete level we deduce that we have a sequence of integers \( n_k \) such that for every \( \delta > 0 \) the event

\[
E_{n_k} = \{\mu_{n_k} B_\varepsilon(x) \leq \delta \text{ and } \mu_{n_k} B_\varepsilon(0) \geq \varepsilon\}
\]

is asymptotically of probability larger than or equal to \( \varepsilon \). As before, we will lighten notation and assume that all the statements involving \( n \) in the following lines have to be restricted to this subsequence. Unsurprisingly, we consider the exploration of the UIHPT by an SLE\(_6\). Since the SLE\(_6\) process is independent of the map (and thus of its uniformization) conditionally on \( \mathcal{T}_{\infty,\infty} \) (and a fortiori on \( E_n \)) there is a positive probability \( c > 0 \) (depending on \( x \) and \( \varepsilon \), but not on \( \delta \)) that the curve \( \gamma \) touches the interval \( [x - \varepsilon, x + \varepsilon] \) then touches \( \mathbb{R}_- \) and finally touches the interval \( [x - \varepsilon, x + \varepsilon] \) again, that is with our notation

\[
P(\text{ComSLE}(x - \varepsilon, x + \varepsilon) \geq 5) > c.
\]

Recall now the notation \( t_{\varepsilon,n} \) and \( C^{\text{dist}}(\varepsilon, n) \) from the proof of Proposition* 4. In terms of horodistance process, using (a variant of) Proposition* 3, with high probability these visits in \( [x - \varepsilon, x + \varepsilon] \) by the SLE process can be associated with some peeling time \( k \) such that \( \mathcal{H}^+(k) = \mathcal{H}^+(k + 1/2) \) where
\( \mathcal{H}^+(k) \in (\varepsilon n, n) \). That is with some time \( \tau^{(k)}(t_{\varepsilon,n}) \) and \( \tau^{(k+2)}(t_{\varepsilon,n}) \) for \( k \leq C_{\text{dis}}(\varepsilon,n) \). By definition of the event \( E_n \), for large \( n \geq 0 \) we have

\[
P\left( \exists k \leq C_{\text{dis}}(\varepsilon,n) : \left| \mathcal{H}^+(\tau^{(k)}(t_{\varepsilon,n})) - \mathcal{H}^+(\tau^{(k+2)}(t_{\varepsilon,n})) \right| \leq \delta_n > c' \right) > 0,
\]

for some positive constant \( c' > 0 \) (depending on \( x \) and \( \varepsilon \) but not on \( \delta \)). Taking the scaling limit of the horodistance processes using Theorem* 2, a similar statement must hold for the stable processes \((S^+, S^-)\) more precisely: There exists some constant \( c'' > 0 \) such that for any \( \delta > 0 \) we have

\[
P\left( \exists k \leq \text{ComStable}(\varepsilon,1) : \left| S^+(\xi^{(k)}(\vartheta_{\varepsilon})) - S^+(\xi^{(k+2)}(\vartheta_{\varepsilon})) \right| \leq \delta > c'' \right) > 0.
\]

Letting \( \delta \to 0 \) we reach a contradiction since \( k \mapsto S^+(\xi^{(k)}(\vartheta_{\varepsilon})) \) is strictly decreasing a.s. \( \Box \)

5 Discussion and comments

First of all, let us mention that although this paper was focused on the case of triangulations, we do not perceive any conceptual obstacle in deriving the same results (provided that a variant of \((\ast)\) holds) for other classes of maps like quadrangulations or general planar maps. Indeed, though the peeling transitions of Section 1.2 are more complicated, they exhibit the same large-scale property and a variant of Proposition 2 should hold (see [5]).

In the next section we give a few elements supporting condition \((\ast)\). We then show how our work naturally triggers new questions related to the links between \( \text{SLE}_6 \) and the GFF which might directly be attacked in the continuous world.

5.1 Discussion on the \((\ast)\) property

We give here some elements supporting \((\ast)\).

- First of all, we have seen in Proposition 6 that the tail of \( \eta_i^+ \) is very light and that \( \eta_i^+ \leq \log^{5+\varepsilon} i \) eventually. We believe that the exponent 5 could be brought down to 1 with some work. Thus only a collective behavior of the \( \eta_i^+ \) could violate \((\ast)\).

- Although not independent, the \( \eta_i^+ \) decorrelate. Quantifying the speed of mixing is a path towards a proof of \((\ast)\). In particular, it happens that during the exploration the \( \text{SLE}_6 \) creates a “bubble”: it explores for some time a new region connected to the past by a single triangle. This roughly corresponds to continuous level to the pinch-points of the \( \text{SLE}_6 \). On an intuitive level the \( \eta_i^+ \) in such a region can be thought as independent of the past.

- Another heuristic for the decorrelation of the \( \eta_i^+ \) is the following. On a rough level, one can imagine that \( \eta_i^+ \) is correlated with \( \eta_j^+ \) with \( i < j \) if during the \( j \)th peeling step the curve \( \gamma \) comes back close to its location at time \( i \) and touches a part of the continuous hull which was close (say within horodistance 10) from the edge \( a_i \):

\[
\eta_i^+ \text{ correlated with } \eta_j^+ \iff \left\{ \begin{array}{l}
\text{The edge } a_i \text{ is still on the boundary of } K_j \\
\text{and } \mathcal{H}^+(j) \approx \mathcal{H}^+(i)
\end{array} \right\}.
\]

However, it is easy to see that when \( a_i \) is still on the boundary of \( K_j \) and \( |\mathcal{H}^+(j) - \mathcal{H}^+(i)| \leq 100 \) then conditionally on the past there is probability bounded away from 0 that the next peeling
step will swallow $a_i$. Our heuristic thus suggests

$$E[\eta_i^+ \sum_{j \geq i} \eta_j^+] \approx E \left[ \sum_{j \geq i} 1_{a_i \in \partial K_j} 1_{H^+(j) \approx H^+(i)} \right]$$

$$\approx E \left[ \sum_{j \geq i} 1_{a_i \in \partial K_j} 1_{|H^+(j) - H^+(i)| \leq M} \right] < \infty.$$  

If this were true we would have $E[(\sum_{i \leq n} \eta_i^+)^2] \leq Cn$ for some $C > 0$ and by Markov inequality $\sum_{i \leq n} \eta_i^+$ could not be much larger than $\sqrt{n}$ (condition (*) just needs $o(n^{2/3})$).

**Percolation interface.** Recall from Remark 2 that Theorem* 2 and Theorem 3 show that the interfaces in critical site percolation on the UIHPT (see Theorem 3) converge, in terms of horodistances, towards the SLE$_6$ exploration. Obviously, one can wonder if a geometric statement holds: Conditionally on $T_{\infty,\infty}$ sample a critical site percolation (with parameter $1/2$) with boundary condition black-white as in Section 2.1. Recall that this naturally defines a percolation interface on the Riemann surface $\mathbb{T}_{\infty,\infty}$ (join with straight lines the middle of the edges $\bullet - \circ$ in each peeled triangle), see Fig.11. Denote by $\mathcal{P}$ the image of this interface on the uniformization $\mathcal{F}_{\infty,\infty}$.

**Question 2.** Show that $\lambda \cdot \mathcal{P}$ converges as $\lambda \to 0$ in distribution towards a standard SLE$_6$ on $\mathbb{H}$.

### 5.2 Towards a characterization of $\mu$

In this section we denote by $\mu$ a possible subsequential limit of the random measures $\mu_n$. A first natural question is to sharpen Proposition* 4 to get a (more) precise result on the location $X_n$ of the $n$th vertex on the right of the root in the uniformized UIHPT:

**Question 3.** Prove that $\frac{\log X_n}{\log n} \to 3$ in probability as $n \to \infty$. Do we actually have $n^{-3}X_n$ tight?

In this work, we only gave little information about $\mu$ but our approach could maybe yield more powerful results. Indeed, the basic idea of this work is to understand $\mu$ through the number of commutings an SLE$_6$ does between some fixed time. We wonder whether such properties could characterize the law of the measure $\mu$ itself. To clarify this point, let us ask a precise question in terms of SLE$_6$.

Fix $x \geq 0$ and consider a rectangle $\mathbb{R}_x$ whose height is 1 and length is $x$. We start an SLE$_6$ in $\mathbb{R}_x$ in the upper-left corner and consider the number $N_x$ of times the exploration alternatively touches the top and bottom boundaries. It is quite easy to guess that the mean of $N_x$ is strictly increasing in $x$ and thus characterizes $x$, see the work of Hongler and Smirnov [20] for an exact expression for $E[N_x]$. We now imagine that the length $X \geq 0$ of the rectangle is random and independent of the SLE$_6$. We still have access to the number $N_X$ of alternative visits of the top and bottom boundaries of the rectangle and wonder:

**Question 4.** Does the distribution of $N_X$ characterize the law of $X$?

If true, this would represent a big step towards the characterization of the law of $\mu$. Indeed, in our work we have access to the analog of $N_X$ in terms of alternated minimal records of two independent $3/2$-stable processes. Note that we are not asking for a procedure to recover $X$ from $N_X$ but just the fact that the later characterizes the former. Indeed, we already possess the candidate for the
limiting random measure (see Question 1) for which we should be able to see this property in the continuous setting:

**GFF, SLE and stable processes.** In what follows \( \varrho = \sqrt{8/3} \). Let \( \gamma \) be an SLE\(_6\) on \( \mathbb{H} \) starting from 0 and denote by \( \Gamma^+ = \gamma \cap \mathbb{R}_+ \) and \( \Gamma^- = \gamma \cap \mathbb{R}_- \). Independently of \( \gamma \) let \( \mu_\varrho \) be the boundary measure constructed using a Gaussian free field as in the Introduction, and let \( F^+(t) = \mu_\varrho[0,t] \) for \( t \geq 0 \) and similarly \( F^-(t) = \mu_\varrho[t,0] \) for \( t \leq 0 \). On the other hand let \( S^+ \) and \( S^- \) be two independent stable processes and recall the notation \( S^+ \) and \( S^- \) for their running infimum processes. We also write \( M^+ = S^+(\mathbb{R}_+) \) and \( M^- = S^-(\mathbb{R}_+) \) for the range of these processes.

**Question 5.** Show that we have

\[
\left( F^+(\Gamma^+), F^-(\Gamma^-) \right) \overset{(d)}{=} - (M^+, M^-).
\]

On a rough (and imprecise level) when running an SLE\(_6\) process on the plane then the “quantum” lengths (defined with an independent Gaussian free field and with the parameter \( \varrho = \sqrt{8/3} \)) created and swallowed on the left and on the right of the tip of the exploration form two independent \( 3/2 \)-stable processes.

The above conjecture should also hold for general SLE\( _\kappa \) for \( \kappa \in (4, 8) \) provided that the parameter of the GFF is tuned to \( \varrho = \sqrt{16/\kappa} \). In this case the independent stable processes appearing should be of index \( \kappa/4 \in (1, 2) \).

### 5.3 Full-plane

To conclude, we would like to mention that our tools might be extended to investigate the conformal structure of random maps “in the bulk”. Similarly as in this work, the limiting random measures in the plane induced by the conformal uniformization of random planar maps is conjectured to be described by the exponential of the GFF with the same parameter \( \varrho = \sqrt{8/3} \) and should be of fractal dimension 2/3.

Contrary to what we have done here, one should use a full-plane version of the SLE\(_6\) instead of the chordal version. Again, the locality property of the SLE\(_6\) will imply that the exploration is Markovian (see [4, 9] for Markovian exploration of the UIPT/UIPQ) and thus under a similar \((*)\) condition one would be able to understand the change in the boundary length on the left and right of the peeling point. Two difficulties will then arise: first the scaling limit of the variations of the boundary length in a full-plane exploration (of the UIPT say) now involves \( 3/2 \)-stable processes conditioned to survive, second the geometric property (bouncing on the real line) used in this work has to be replaced by another geometric property computable in terms of the “horodistances”: the winding number. We cherish the hope of pursuing these ideas in future works.
