The quantum fluctuations of the entropy production for fermionic systems in the Landauer-Büttiker non-equilibrium steady state are investigated. The probability distribution, governing these fluctuations, is explicitly derived by means of quantum field theory methods and analysed in the zero frequency limit. It turns out that microscopic processes with positive, vanishing and negative entropy production occur in the system with non-vanishing probability. In spite of this fact, we show that all odd moments (in particular, the mean value of the entropy production) of the above distribution are non-negative. This result extends the second principle of thermodynamics to the quantum fluctuations of the entropy production in the Landauer-Büttiker state. The effect of the time reversal is also discussed.

I. INTRODUCTION

The entropy production is a measure for irreversibility and represents an essential characteristic feature of non-equilibrium systems. In the quantum context the entropy production is fundamental for understanding the deep interplay between microscopic and macroscopic physics and in particular, the second principle of thermodynamics. For this reason the study of the entropy production is receiving a constant attention [1]-[6]. A variety of off-equilibrium states [7]-[10] and different physical systems [11]-[16] have been already analysed. In addition, the equilibrium states [7]-[10] and different physical systems is receiving a constant attention [1]-[6]. A variety of off-equilibrium states and in particular, the second principle of thermodynamics [23], provide universal information about the nature of fluctuation relations which have been established [17]-[22]. The interest in such devises, which are essentially one-dimensional systems whose transport properties are affected by quantum effects, is largely motivated by the fact that they would naturally appear in any quantum circuit. Triggered by the remarkable progress in nanotechnology, the study of quantum wire junctions nowadays dominates the experimental activity in quantum transport. The focus is mainly on the particle and heat transport, but recently the entropy production in quantum circuits [30] and other mesoscopic systems [31] attracts much attention as well.

The basic physical processes, taking place in the system in Fig. 1 can be summarised as follows. A non-vanishing transmission probability \(|S_{12}|^2\) drives the system away from equilibrium, provided that the temperatures and/or chemical potentials are different. The departure from equilibrium is characterised by the presence of incoming and outgoing matter and energy flows from the reservoirs \(R_i\). The study of these flows started with the pioneering work of Landauer [32] and Büttiker [33], who developed an exact scattering approach, going far beyond the linear response approximation. The Landauer-Büttiker (LB) framework is the basis of modern quantum transport theory and has been successfully generalised [34]-[36] and applied to the computation of the noise power [37]-[44] and the full counting statistics [45]-[50].

In what follows we apply the LB approach to the study of the entropy production. We concentrate on fermionic systems, discussing the bosonic case elsewhere [51]. The basic ingredients of our investigation are:

(i) a suitably defined field operator \(\hat{S}(t, x)\), which describes the entropy production;

(ii) a non-equilibrium steady state \(\Omega_{\text{LB}}\), which captures the physical properties of the system shown in Fig. 1.

FIG. 1: (Color online) Two-terminal junction.

In this article we investigate the entropy production in quantum systems which are schematically shown in Fig. 1. Each of the two semi-infinite leads \(L_i\) is attached at infinity to a heat reservoir \(R_i\) with (inverse) temperature \(\beta_i \geq 0\) and chemical potential \(\mu_i \in \mathbb{R}\). The capacity of the reservoirs is assumed to be large enough, so that the processes of emission and absorption of particles do not change the parameters of \(R_i\). A point-like defect is localised at \(x = 0\) and is described by a unitary scattering matrix \(S\).

The system in Fig. 1 models a quantum wire junction [24]-[29]. The interest in such devises, which are...
With this input, all the information about the entropy production is codified in the sequence of $n$-point correlation functions ($n = 1, 2, \ldots$)

$$w_n[\hat{S}](t_1, x_1, \ldots, t_n, x_n) = \langle \hat{S}(t_1, x_1) \cdots \hat{S}(t_n, x_n) \rangle_{\Omega_{\text{LB}}} ,$$

(1)
the expectation value $\langle \cdots \rangle_{\text{LB}}$ being computed in the LB state $\Omega_{\text{LB}}$.

Previous research in the quantum context has been mainly focussed on $w_1[\hat{S}]$, which describes the mean value of the entropy production. Adopting quantum field theory methods, we address in this paper the problem of the quantum fluctuations, which are fully characterised by (1) with $n \geq 2$. The correlation functions $w_n[\hat{S}]$ depend on $2n$ space-time variables, which complicate the analysis for large $n$. In order to simplify the problem, we follow the standard approach [43]-[50] to full counting statistics and investigate the zero frequency limit $\mathcal{W}_n[\hat{S}]$ of $w_n[\hat{S}]$, integrating the quantum fluctuations over long period of time. We show that in this limit $\mathcal{W}_n[\hat{S}]$ take the form

$$\mathcal{W}_n[\hat{S}] = \int_0^\infty \frac{d\omega}{2\pi} \mathcal{M}_n(\omega) ,$$

(2)
where $\omega$ is the energy and $\mathcal{M}_n$ are the moments of a probability distribution $\varrho$. The derivation of $\varrho$ represents a key point of our investigation. In fact, we extract from $\varrho$ the basic information about the entropy production at the microscopic level. The fundamental quantum process, which takes place in our system, is the emission of a particle from the reservoir $R_i$ and the subsequent absorption by $R_j$. We derive from $\varrho$ the probability $p_{ij}$ for this event at any energy $\omega$ and determine the corresponding entropy production

$$\sigma_{ij} = [(\beta_i - \beta_j)\omega - (\beta_i \mu_i - \beta_j \mu_j)] |S_{12}| .$$

(3)
In the absence of transmission ($S_{12} = 0$) one has $\sigma_{ij} = 0$ in agreement with the fact that the two heat reservoirs are disconnected and the system is in equilibrium. The antisymmetry of $\sigma_{ij}$ implies furthermore that the entropy production for emission and absorption of a particle by the same reservoir vanishes, as expected on general grounds. Moreover, $\sigma_{12}$ and $\sigma_{21}$ have opposite sign which, combined with the fact that $p_{12} \neq 0$ and $p_{21} \neq 0$, leads to the conclusion that both processes with positive and negative entropy production are necessarily present at the microscopic level. Nevertheless, we demonstrate below that the process with positive entropy production dominates in the state $\Omega_{\text{LB}}$, implying that all moments $\{\mathcal{M}_n(\omega) : \omega \geq 0, n = 1, 2, \ldots\}$ of $\varrho$ obey

$$\mathcal{M}_n(\omega) \geq 0 ,$$

(4)
for any value of the temperatures and chemical potentials of $R_i$. In addition, $\mathcal{M}_n(\omega)$ vanishes for any $\omega$ only at the equilibrium $\beta_1 = \beta_2$ and $\mu_1 = \mu_2$.

For even $n$ the inequality (4) follows directly from the fact that $\varrho$ is a true probability distribution on $\mathbb{R}$, whereas for odd $n$ it is a consequence of the specific form of $\varrho$. It generalises to the quantum fluctuations the result of Nenciu [7]

$$\langle \hat{S}(t, x) \rangle_{\text{LB}} = \int_0^\infty \frac{d\omega}{2\pi} \mathcal{M}_1(\omega) \geq 0$$

(5)
about the mean value of the entropy production in $\Omega_{\text{LB}}$, which provides a bridge between microscopic quantum physics and the second law of thermodynamics. In this respect, the bound (5) represents an extension of the second principle to the quantum fluctuations of the entropy production. The result (5) is an intrinsic characteristic feature of the LB state. To our knowledge no other steady states with this property are presently known.

The paper is organised as follows. In the next section we describe the basic physical properties of the system. We also introduce the entropy production operator $\hat{S}$ and the LB representation incorporating the non-equilibrium properties of the system in Fig. 1. The $n$-point correlation functions of $\hat{S}$ in the LB state $\Omega_{\text{LB}}$ are derived in section III. In section IV we reconstruct the probability distribution $\varrho$ associated with the entropy production, solving the corresponding moment problem. The physical properties of $\varrho$ are discussed and the role of time reversal is elucidated. It is also shown that the presence of a galvanometer in the system does not modify the bound (5). Section V is devoted to our conclusions. Finally, the appendices collect some technical details.

II. PRELIMINARIES

In this section we summarise the basic non-equilibrium features of quantum systems of the type shown in Fig. 1. Throughout the paper we adopt the following coordinates $\{(x, i) : x \leq 0, i = 1, 2\}$, where $|x|$ denotes the distance from the defect and $i$ labels the lead.

A. Conserved currents and entropy production

Let us start by fixing the symmetry content. We consider in this paper physical systems in which both the particle number and the total energy are conserved. Accordingly, the correlation functions are invariant under global $U(1)$ transformations and time translations. These symmetries imply the existence of a conserved particle and energy currents $(j_1, j_2)$ and $(\theta_{tt}, \theta_{xt})$. Local conservation implies

$$\partial_t j_i(t, x, i) - \partial_x j_x(t, x, i) = 0 ,$$

(6)
$$\partial_t \theta_{tt}(t, x, i) - \partial_x \theta_{xt}(t, x, i) = 0 .$$

(7)
In order to generate global conserved charges from $j_i$ and $\theta_{tt}$, which define the particle number and total energy respectively, one must impose the Kirchhoff’s rules

$$\sum_{i=1}^2 j_x(t, 0, i) = \sum_{i=1}^2 \theta_{xt}(t, 0, i) = 0 ,$$

(8)
which are assumed in what follows.

The total energy of our system has two components: heat energy and chemical energy. Since the chemical energy density is given by \(\mu_i j_i(t, x, i)\), for the heat density one has

\[
q(t, x, i) = \theta_{tt}(t, x, i) - \mu_i j_i(t, x, i) .
\]

Accordingly, the heat current reads

\[
q_x(t, x, i) = \theta_{xt}(t, x, i) - \mu_i j_x(t, x, i) .
\]

Following [52], we introduce at this point the entropy production operator [3, 7]

\[
\dot{S}(t, x) = -\sum_{i=1}^{2} \beta_i q_x(t, x, i) .
\]

The definition (11) involves the non-equilibrium heat currents flowing in the leads \(L_i\) and the equilibrium temperatures \(\beta_i\) of the heat reservoirs. The operator (11) will be the main subject of our investigation below.

A simple but deep difference between the heat current \(q_x(t, x, i)\) and entropy production operator \(\dot{S}(t, x)\) is worth stressing. The current \(q_x(t, x, i)\) is a local observable, which depends on the lead \(L_1\) where it is observed or measured. The entropy production operator \(\dot{S}(t, x)\) concerns instead the whole system and does not refer to a single lead. Accordingly, the correlation functions (11), which describe the entropy production fluctuations, take into account all the interference effects between the heat currents in the two different leads \(L_1\) and \(L_2\). The contribution of the interference terms to (11) is fundamental for proving the bound (3).

It is instructive at this stage to describe the basic physical process taking place in the system in Fig. 1 and generating the entropy production. The conservation laws (6,7) obviously imply the local heat current conservation

\[
\partial_t q(t, x, i) - \partial_x q_x(t, x, i) = 0 .
\]

However, if \(\mu_1 \neq \mu_2\) the heat current violates the Kirchhoff rule. One has in fact

\[
\sum_{i=1}^{2} q_x(t, 0, i) = (\mu_1 - \mu_2) j_x(t, 0, 1) .
\]

Since the total energy is conserved, both the heat and chemical energies are in general not separately conserved. Therefore, for \(\mu_1 \neq \mu_2\) the junction in Fig. 1 operates as energy converter without dissipation [53]. The two possible regimes are controlled by the expectation value of the operator

\[
\hat{Q} = -\sum_{i=1}^{2} q_x(t, x, i) .
\]

in the underlying non-equilibrium state. If \(\langle \hat{Q} \rangle < 0\) the junction transforms heat to chemical energy. The opposite process takes place if instead \(\langle \hat{Q} \rangle > 0\). A detailed study of this phenomenon of energy transmutation in the LB state \(\Omega_{LB}\) has been performed in [53].

The above general considerations apply to the system in Fig. 1 with any dynamics preserving the particle number and total energy. In this sense they are universal. For concretely evaluating the quantum fluctuations associated with \(\dot{S}\), one should fix the dynamics and the non-equilibrium state. This is done in the next subsection.

B. Dynamics and the LB state - the Schrödinger junction

Non-equilibrium systems of the type in Fig. 1 behave in a complicated way and the linear response or other approximations are usually not enough for fully describing their complexity. For this reason the existence of models, which incorporate the main non-equilibrium features, while being sufficiently simple to be analysed exactly, is conceptually very important. One such example is provided by particles, which are freely moving along the leads and interact only in the junction \(x = 0\). This hypothesis accounts remarkably well [54] for the experimental results [55] about the noise in mesoscopic conductors and has been recently confirmed [56] even in the case of fractional charge transport in quantum Hall samples.

At the theoretical side, our previous analysis in [53], [41], [51] and [42] shows that this setup represents an exceptional testing ground for exploring general ideas about quantum transport.

One concrete realisation of the above scenario is the Schrödinger junction, where the dynamics along the leads is fixed by (the natural units \(\hbar = c = k_B = 1\) are adopted throughout the paper)

\[
\left(i\partial_t + \frac{1}{2m} \partial_x^2\right) \psi(t, x, i) = 0 ,
\]

supplemented by the standard equal-time canonical anticommutation relations. The junction represents physically a point-like defect localised at \(x = 0\). The associated interaction determines the scattering matrix \(S\), which is fixed by requiring that the bulk Hamiltonian \(-\partial_x^2 / 2m\) admits a self-adjoint extension in \(x = 0\). All such extensions are defined [57-59] by the boundary condition

\[
\lim_{x \to 0} \sum_{j=1}^{2} \left(\lambda(\mathbb{I} - U)_{ij} + i(\mathbb{I} + U)_{ij} \partial_x\right) \psi(t, x, j) = 0 ,
\]

where \(\mathbb{I}\) is the identity matrix, \(U\) is a generic \(2 \times 2\) unitary matrix and \(\lambda > 0\) is a parameter with dimension of mass. Eq. (10) guaranties unitary time evolution and implies [57-59] the scattering matrix

\[
S(k) = \frac{[\lambda(\mathbb{I} - U) - k(\mathbb{I} + U)]}{[\lambda(\mathbb{I} - U) + k(\mathbb{I} + U)]} ,
\]
k being the particle momentum. Equation (17) defines a
meromorphic function in the complex k-plane.

Since scale invariance preserves the universal properties
of one-dimensional quantum transport [61] and leads at
the same time to relevant simplifications, it is instructive
to characterise explicitly the scale invariant elements in
the family (17). For this purpose we first diagonalise U

\[ \mathcal{U}^* U = \mathcal{U}_d = \text{diag}(e^{-2i\alpha_1}, e^{-2i\alpha_2}), \]

where * stands for Hermitian conjugation. It follows from
(17) that the unitary matrix \( U \) diagonalises \( S(k) \) for
any \( k \) as well. In fact

\[ S_d(k) = \mathcal{U}^* S(k) \mathcal{U} = \text{diag} \left( \frac{k + i\eta_1}{k - i\eta_1}, \frac{k + i\eta_2}{k - i\eta_2} \right), \]

where

\[ \eta_i \equiv \lambda \tan(\alpha_i). \]  

At this point scale invariance implies [29, 61] the following
alternative

\[ \eta_i = \begin{cases} 0 & (\alpha_i = 0), \\ \infty & (\alpha_i = \pi/2), \end{cases} \]

\text{Neumann b.c.,} \quad \text{Dirichlet b.c.} \]  

(21)

Accordingly, the scale invariant scattering matrices,
called also critical points, are \( k \)-independent and are
given by the family

\[ S = \mathcal{U} S_d \mathcal{U}^*, \quad U \in U(2), \quad S_d = \text{diag}(1, -1) \]  

(22)

supplemented by the two isolated elements \( S = \pm i \). The
latter are not interesting because there is no transmission
between the two leads and the system is therefore in

\[ \chi(k; x) = \left[ e^{-i\omega k} + e^{i\omega k} \right] \mathcal{S}(k) \], \quad \omega \geq 0, \]

(23)

Postponing the discussion of the general case, let us assume
for the moment that \( \mathcal{S}(k) \) has no bound states. Then, the
solution of the quantum boundary value problem

\[ \chi(k; x) = \left[ e^{-i\omega (k) t} + e^{i\omega (k) t} \right] \mathcal{S}(k) \]

(24)

where \( \omega(k) = k^2/2m \) is the dispersion relation and the
operators \( \{a_i(k), a_i^*(k) : k \geq 0, i = 1, 2\} \) generate a
standard anti-commutation relation algebra \( A_+ \).

Both (15) and (16) are invariant under global \( U(1) \)
phase transformations and time translations. The relative
conserved particle and energy currents have the well
known form

\[ j_x(t, x, i) = \frac{i}{2m} \left[ \psi^*(\partial_x \psi) - (\partial_x \psi^*) \psi \right](t, x, i), \quad \]

(25)

and

\[ \theta_x(t, x, i) = \frac{1}{4m} \left[ (\partial_x \psi^*) (\partial_x \psi) + (\partial_x \psi^*) (\partial_t \psi) \right. \]

\[ - (\partial_t \psi^*) \psi - (\partial_t \psi^*) (\partial_x \psi) \right](t, x, i), \]

(26)

respectively. Plugging the solution (24) in (25,26), one
can express the heat current (10) and therefore the
entropy production field operator in terms of the generators
of \( A_+ \). The result is

\[ \mathcal{S}(t, x) = \frac{i}{4m} \int_0^\infty \frac{dk}{2\pi} \int_0^\infty \frac{dp}{2\pi} e^{i[k - \omega(p)]t} \]

\[ \times \sum_{l,j=1}^2 \sum_{i=1}^2 \beta_i [2\mu_i - \omega(k) - \omega(p)] \left\{ \chi^*_l(k; x) \left[ \partial_x \chi_{ij} \right] (p; x) - \left[ \partial_x \chi^*_l \right] (k; x) \chi_{ij} (p; x) \right\} a_j(p). \]

(27)

This equation defines \( \mathcal{S}(t, x) \) as a quadratic element of the
algebra \( A_+ \). In order to extract the physical information
we are interested in, one must fix a representation of \( A_+ \).

The physical setup in Fig. 1 suggests to adopt the LB
representation of \( A_+ \), which generalises the equilibrium
Gibbs representation to the case of systems driven away
from equilibrium by a particle and energy exchange with
more than one heat reservoir. A field theoretical
construction of the Hilbert space \( \mathcal{H}_{LB}, \langle \cdot, \cdot \rangle \) of this
representation is given in [62]. For deriving the expectation

values of (27) one can concentrate on the 2n-point function

\[ \Omega_{LB} \equiv \langle a^*_1(k_1)a_{m_1}(p_1) \cdots a^*_n(k_n)a_{m_n}(p_n) \rangle_{LB} \]

(28)

which can be represented as a kind of Slater determinant,
whose explicit form [A3] is given in appendix A. Using
[A3] we derive in what follows the correlation functions of
the operator \( \mathcal{S} \) in the LB representation \( \mathcal{H}_{LB} \) and discuss the
physical implications.
III. ENTROPY PRODUCTION CORRELATION FUNCTIONS

A. The one-point function

It is natural to start with the one point function \( \langle \dot{S}(t,x) \rangle_{\text{LB}} \), which gives the mean value of the entropy production in the LB state \( \Omega_{\text{LB}} \). Using (27) and (A3) for \( n = 1 \), one easily obtains the integral representation (5) with

\[
\mathcal{M}_1(\omega) = \tau(\omega) [\gamma_2(\omega) - \gamma_1(\omega)] [d_1(\omega) - d_2(\omega)].
\]

Here

\[
\tau(\omega) = |S_{12}(\sqrt{2\beta \omega})|^2
\]

is the transmission probability,

\[
\gamma_i(\omega) = \beta_i(\omega - \mu_i), \quad i = 1, 2
\]

and \( d_i(\omega) \) is the Fermi distribution

\[
d_i(\omega) = \frac{1}{1 + e^{\beta_i(\omega)}}
\]

\[
\langle \dot{S}(t,x) \rangle_{\text{LB}} = (\lambda_2 - \lambda_1) \frac{\tau}{2\pi} \left[ \frac{1}{\beta_2} \ln (1 + e^{\lambda_2}) - \frac{1}{\beta_1} \ln (1 + e^{\lambda_1}) \right] + (\beta_1 - \beta_2) \frac{\tau}{2\pi} \left[ \frac{1}{\beta_1^2} \text{Li}_2(-e^{\lambda_1}) - \frac{1}{\beta_2^2} \text{Li}_2(-e^{\lambda_2}) \right].
\]

where \( \lambda_i \equiv \beta_i \mu_i \) are dimensionless parameters and \( \text{Li}_2 \) is the dilogarithm function.

![FIG. 2: (Color online) Entropy production (in temperature units) for \( \beta_1 = \beta_2 = \beta \) and \( \tau = 1/2 \) with \( (\mu_1, \mu_2) = (-30, -10) \) (red line), \( (-5, 0) \) (blue line) and \( (4, 6) \) (black line).](image)

The mean value the entropy production \( \mathcal{M}_1(\omega) \) is generated by both the temperature and the chemical potential differences of the heat reservoirs. In order to get an idea about the separate effect of these two independent sources, it is instructive to consider the limiting regimes of the reservoir \( R_i \). One can easily check now that both square brackets \([-\cdot] \) of (29) have always the same sign or vanish simultaneously. Therefore,

\[
\mathcal{M}_1(\omega) \geq 0,
\]

which proves (4) for \( n = 1 \). In addition, \( \mathcal{M}_1(\omega) = 0 \) for any \( \omega \) implies the equilibrium regime \( \beta_1 = \beta_2 \) and \( \mu_1 = \mu_2 \).

It is worth mentioning that \( \langle \dot{S}(t,x) \rangle_{\text{LB}} \), given by (5, 29), is both time and position independent. The \( t \)-independence follows from the energy conservation, whereas the \( x \)-independence is a consequence of the heat current conservation (12). Clearly, these are peculiar properties of the one-point function \( w_n[S] \). The study of \( \{w_n[S], n \geq 2\} \) in the next subsection reveals a more complicated behaviour.

Let us assume first that that the heat reservoirs have the same temperature \( \beta_1 = \beta_2 = \beta \). In this regime the dilogarithms in (34) do not contribute and at high temperature one finds

\[
\lim_{\beta \to 0} \langle \dot{S}(t,x) \rangle_{\text{LB}}^{\beta_1 = \beta_2} = 0.
\]

The behaviour at low temperature depends on \( \mu_1 \). Observing that \( \langle \dot{S}(t,x) \rangle_{\text{LB}}^{\beta_1 = \beta_2} \) is a symmetric function of \( (\mu_1, \mu_2) \), one can assume without loss of generality that \( \mu_1 < \mu_2 \) and obtain

\[
\lim_{\beta \to \infty} \langle \dot{S}(t,x) \rangle_{\text{LB}}^{\beta_1 = \beta_2} = \begin{cases} 0, & \text{for } \mu_2 < 0, \\ -\frac{\pi \tau^2 \ln 2}{2\pi}, & \text{for } \mu_2 = 0, \\ \infty, & \text{for } \mu_2 > 0, \end{cases}
\]

as shown in Fig. 2.

In the second case we set \( \mu_1 = \mu_2 = \mu \). The origin of the entropy increase is therefore exclusively the difference between the temperatures \( \beta_1 \neq \beta_2 \) of the two heat reservoirs. In this case the dilogarithms in (34) have a
In fact, using the definition (27) of \( \dot{S} \) becomes actually the whole line. We show in appendix B relevant contribution, \( \langle \dot{S}(t, x) \rangle_{\text{LH}}^{\mu_1=\mu_2} \) is a symmetric function of \((\beta_1, \beta_2)\) and one has
\[
\lim_{\mu \to -\infty} \langle \dot{S}(t, x) \rangle_{\text{LH}}^{\mu_1=\mu_2} = 0,
\]
\[
\lim_{\mu \to \infty} \langle \dot{S}(t, x) \rangle_{\text{LH}}^{\mu_1=\mu_2} = \frac{\pi(\beta_1 - \beta_2)^2(\beta_1 + \beta_2)\tau}{12\beta_1^2\beta_2^2},
\]

\[
W_n[\dot{S}](x_1, ..., x_n; \nu) = \int_{-\infty}^{\infty} \cdots \int_{-\infty}^{\infty} d\tau_1 \cdots d\tau_n e^{-i\nu(\tau_1 + \cdots + \tau_n - 1)} w_n[\dot{S}](t_1, x_1, ..., t_n, x_n), \quad n \geq 2,
\]
and perform the zero-frequency limit
\[
W_n[\dot{S}] = \lim_{\nu \to 0^+} W_n[\dot{S}](x_1, ..., x_n; \nu).
\]

This limit has been adopted already in the classical studies \cite{37,41} of quantum noise produced by the particle current for \( n = 2 \). It has been extended in \cite{48} to the current cumulants with \( n > 2 \) and applied in the framework of full counting statistics \cite{43,44,50} as well. The zero frequency regime has a well known physical meaning and is mostly explored in experiments. As mentioned in the introduction, in the range of low frequencies all quantum fluctuation are integrated over long period of time. It is evident from \cite{39} that in the limit \( \nu \to 0 \) this period becomes actually the whole line. We show in appendix B that the structure of \( w_n[\dot{S}] \) greatly simplifies in this case. In fact, using the definition \cite{27} of \( \dot{S} \) and the correlation function \cite{13}, one finds
\[
W_n[\dot{S}] = \int_0^{\infty} \frac{d\omega}{2\pi} [\gamma_2(\omega) - \gamma_1(\omega)]^nw_n(\omega).
\]

The basic steps in deriving the representation \cite{41}, as well as the explicit form \cite{32} of the factor \( \mathbb{D}_n(\omega) \) in the integrand, are given in appendix B. \( \mathbb{D}_n(\omega) \) is a sum of determinants, which depend on the scattering matrix \cite{17} and the Fermi distribution \cite{32}, in other words on \( \tau(\omega) \) and \( (\beta_i, \mu_i) \). It has been shown in \cite{42} that the bound states of \( \dot{S} \), if they exist, do not contribute in the limit \cite{40} as well. Despite of these significant simplifications, at the first sight the integrand of \cite{41} for generic \( n \) might look still complicated. As shown in appendix B however, this is not the case and the final expression reads
\[
W_n[\dot{S}] = \int_0^{\infty} \frac{d\omega}{2\pi} \mathcal{M}_n(\omega),
\]
with
\[
\mathcal{M}_{2k-1} = \tau^k(\gamma_2 - \gamma_1)^{2k-1} c_1, \quad \mathcal{M}_{2k} = \tau^k(\gamma_2 - \gamma_1)^{2k} c_2.
\]

Here \( k = 1, 2, ..., \) the \( \omega \)-dependence of all factors has been suppressed for conciseness and the following combinations
\[
c_1 \equiv d_1 - d_2, \quad c_2 \equiv d_1 + d_2 - 2d_1d_2,
\]
have been introduced for convenience. The explicit form \cite{43,44} of the integrands \( \mathcal{M}_n \) represents a key point of our analysis of the fluctuations of the entropy production. First of all, from \cite{43,44} one infers the result \cite{4} announced in the introduction, namely that all \( \mathcal{M}_n \) are nonnegative. In fact, the argument about the
positivity of $\mathcal{M}_1$ applies actually for all odd values of $n$. The inequality (41) for even values of $n$ follows instead from
\[
c_2 = \frac{e^{\gamma_1} + e^{\gamma_2}}{1 + e^{\gamma_1}} \geq 0.
\]
(46)

Our goal in the next section will be to show that the integrands (43,44) represent indeed the moments of a probability distribution and to reconstruct this distribution.

IV. PROBABILITY DISTRIBUTION GOVERNING THE ENTROPY PRODUCTION

The fluctuations of a quantum observable give rise in general to a quasi-probability distribution. Familiar examples are the Wigner function [63], some distributions stemming from coherent states in quantum optics [64,65] and more recent examples associated with time-integrated observables [66,67] in the context of full quantum statistics [43-47]. In this section we show that $\mathcal{S}$ generates in the LB state $\Omega_{\text{LB}}$ a true probability distribution $\varrho$. The idea is to reconstruct $\varrho$ from the moments (43,44), solving the underlying moment problem.

A. Solution of the moment problem

We are looking for a function $\varrho$ with domain $\mathcal{D}$ such that
\[
\mathcal{M}_n = \int_{\mathcal{D}} d\sigma \, \sigma^n \varrho(\sigma), \quad n = 0, 1, \ldots,
\]
(47)
where $\mathcal{M}_n$ are given for $n \geq 1$ by (43,44) and
\[
\mathcal{M}_0 = 1
\]
(48)
provides a normalisation condition. The parameter $\sigma$ describes the entropy production. There exist [68] three possible choices for the domain $\mathcal{D}$ of $\sigma$: the whole line $\mathcal{D} = \mathbb{R}$, the half line $\mathcal{D} = \mathbb{R}_+$ and a compact interval $\mathcal{D} = [a,b]$. In order to determine $\mathcal{D}$ we have to investigate the Hankel determinants
\[
\mathbb{H}_n \equiv \begin{vmatrix}
\mathcal{M}_0 & \mathcal{M}_1 & \cdots & \mathcal{M}_n \\
\mathcal{M}_1 & \mathcal{M}_2 & \cdots & \mathcal{M}_{n+1} \\
\vdots & \vdots & \ddots & \vdots \\
\mathcal{M}_n & \mathcal{M}_{n+1} & \cdots & \mathcal{M}_{2n}
\end{vmatrix}.
\]
(49)

A necessary and sufficient condition for the existence of $\varrho$ on $\mathbb{R}$ is [68]
\[
\mathbb{H}_n \geq 0, \quad \forall n = 1, 2, \ldots
\]
(50)
Using (43,44,48) one gets
\[
\mathbb{H}_{n=0} = 1, \quad \mathbb{H}_1 = \tau(\gamma_1 - \gamma_2)^2(c_2 - \tau c_1^2), \quad \mathbb{H}_2 = \tau^3(\gamma_1 - \gamma_2)^6(1 - c_2)(c_2^2 - \tau c_1^2), \quad \mathbb{H}_{n \geq 3} = 0.
\]
(51)

Combining the inequalities
\[
0 \leq c_2 \leq 1, \quad c_2^2 - c_1^2 \geq 0,
\]
(53)
which follow directly from the explicit form (45) of $c_i$ and using $0 \leq \tau \leq 1$, one gets that both $\mathbb{H}_1$ and $\mathbb{H}_2$ are non-negative. Since in addition,
\[
\mathbb{H}_2 = \left| \frac{\mathcal{M}_1 \mathcal{M}_2 \mathcal{M}_3}{\mathcal{M}_2 \mathcal{M}_3 \mathcal{M}_4} \right| = \tau^2(\gamma_1 - \gamma_2)^4(\gamma_1^2 + \gamma_2^2 - c_2) \leq 0,
\]
(54)
the domains $\mathbb{R}_+$ and $[a,b]$ are excluded [68].

Summarising, the entropy production $\sigma$ in the LB state $\Omega_{\text{LB}}$ gives rise to the so called Hamburger moment problem $\mathcal{D} = \mathbb{R}$. Moreover, since $\mathbb{H}_{n \geq 3} = 0$ the general theory [68] implies that $\varrho$ is fully localised at three different values of $\sigma$.

Once the domain $\mathcal{D}$ has been determined, the explicit form of the distribution $\varrho$ can be recovered [68] by performing the Fourier transform
\[
\varrho(\sigma) = \int_{-\infty}^{\infty} \frac{d\lambda}{2\pi} e^{-i\lambda\sigma} \varphi(\lambda)
\]
(55)
of the generating function
\[
\varphi(\lambda) = \sum_{n=0}^{\infty} \frac{(i\lambda)^n}{n!} \mathcal{M}_n.
\]
(56)
Employing (43,44,48) one finds
\[
\varphi(\lambda) = 1 + i c_1 \sqrt{\tau} \sin \left[ \lambda(\gamma_2 - \gamma_1) \sqrt{\tau} \right] + c_2 \left\{ \cos \left[ \lambda(\gamma_2 - \gamma_1) \sqrt{\tau} \right] - 1 \right\},
\]
(57)
whose Fourier transform reads
\[ \varrho(\sigma) = \frac{1}{2}(c_2 - c_1 \sqrt{\tau}) \delta[\sigma - (\gamma_1 - \gamma_2)\sqrt{\tau}] + (1 - c_2) \delta(\sigma) + \frac{1}{2}(c_2 + c_1 \sqrt{\tau}) \delta[\sigma - (\gamma_2 - \gamma_1)\sqrt{\tau}] . \]

Equation (58) confirms that the entropy production is indeed localised in three points on the \( \sigma \)-line. It is convenient to adopt at this stage the variables \( \sigma_{ij} \) defined by (59), which read

\[ \sigma_{ij} = (\gamma_i - \gamma_j)\sqrt{\tau} \]

in terms of \( \gamma_i \) and \( \tau \). Then \( \varrho \) can be rewritten the form

\[ \varrho(\sigma) = p_{12} \delta(\sigma - \sigma_{12}) + p \delta(\sigma) + p_{21} \delta(\sigma - \sigma_{21}) \]

with

\[ p_{12} = \frac{1}{2}(c_2 - c_1 \sqrt{\tau}), \quad p_{21} = \frac{1}{2}(c_2 + c_1 \sqrt{\tau}), \quad p = 1 - c_2 . \]

Here \( p_{ij} \) is the probability of emission of a particle by the reservoir \( R_i \) and absorption by \( R_j \), whereas \( p \) is the probability for emission and absorption by the same reservoir \( R_1 \) or \( R_2 \). One can easily show in fact that

\[ p_{12} + p + p_{21} = 1 , \quad p_{ij} \in [0,1], \quad p \in [0,1] , \]

implying that \( \varrho \) is a true probability distribution.

It is worth stressing that the probabilities (62) refer to arbitrary but fixed energy \( \omega \in [0,\infty) \). At this energy the probabilities for \( n \)-particle emission and absorption with \( n \geq 2 \) vanish because of Pauli’s principle. This is not the case for the bosonic junctions discussed in [51], where multi-particle emission/absorption processes with the same energy are allowed.

As anticipated in the introduction, we have shown that both processes with positive and negative entropy production appear at the quantum level. It is quite intuitive that if the transport of a particle from the red to the blue reservoir in the isolated system in Fig. 1 increases the entropy, the opposite process is decreasing it. The crucial point is that according to (61) both these events have a non-vanishing probability and are present without invoking any time reversal operation.

Since \( \varrho \) is not a smooth but a generalised function, in order to illustrate graphically its behaviour it is convenient to introduce the \( \delta \)-sequence

\[ \delta_\nu(\sigma) = \frac{\nu}{\sqrt{\pi}} e^{-\nu^2 \sigma^2} , \quad \nu > 0 , \]

and consider the smeared distribution

\[ \varrho_\nu(\sigma) = p_{12} \delta_\nu(\sigma - \sigma_{12}) + p \delta_\nu(\sigma) + p_{21} \delta_\nu(\sigma - \sigma_{21}) . \]

As well known, for \( \nu \to \infty \) one has \( \varrho_\nu \to \varrho \) in the sense of generalised functions. The plots of \( \varrho_\nu \) for finite values of \( \nu \) nicely illustrate the physics behind the distribution \( \varrho \). One example is reported in Fig. 4 The shape of \( \varrho_\nu \) depends on \( \nu \), but the events with positive entropy production always dominate those with negative one. This feature is a consequence of the property

\[ \sigma_{ij} > 0 \implies p_{ij} > p_{ji} , \]

which is \( \nu \)-independent and holds therefore also in the limit \( \nu \to \infty \).

![Graph](image)

**FIG. 4:** (Color online) The smeared distribution \( \varrho_\nu \) with \( \nu = 2/3, \gamma_1 = 21, \gamma_2 = 1 \) and \( \tau = 1/4 \).

It is instructive in this point to derive the ratio \( P_+/P_- \) where \( P_\pm \) is the probability to have positive/negative entropy production. Without loss of generality one can assume for this purpose that \( \sigma_{12} > 0 \). Then

\[ \frac{P_+}{P_-} = \frac{p_{12}}{p_{21}} = \frac{c_2 - c_1 \sqrt{\tau}}{c_2 + c_1 \sqrt{\tau}} = \frac{(1 - \sqrt{\tau}) + (1 + \sqrt{\tau}) e^{\sigma_{12}/\sqrt{\tau}}}{(1 + \sqrt{\tau}) + (1 - \sqrt{\tau}) e^{\sigma_{12}/\sqrt{\tau}}} . \]

Equation (67) generalises the fluctuation relation, discussed in [17, 23], to the case in which space translation invariance is broken by a quantum point-like defect with transmission probability \( \tau \). In the limit \( \tau \to 1 \) the defect disappears, the system becomes homogeneous and one recovers from (66) the result of Crooks [17]

\[ \lim_{\tau \to 1} \frac{P_+}{P_-} = e^{\sigma_{12}} , \]

originally obtained in the context of stochastic dynamics.

Summarising, the probability distribution (58) fully describes the entropy production zero-frequency fluctuations in the LB state \( \Omega_{LB} \). It is natural to expect that the behaviour of \( \varrho \) depends on the choice of this state. This expectation is confirmed in the next subsection, where the \( S \)-fluctuations in the state generated from \( \Omega_{LB} \) by time reversal are explored.
B. Impact of time reversal

As before, we consider the field $\psi$ defined by (24) in the LB representation $\{H_{\text{LB}}, (\cdot, \cdot)\}$ of the algebra $\mathcal{A}_+$. The time reversal operation acts as usual

$$T\psi(t, x, i)T^{-1} = \eta_T \psi(-t, x, i),$$

where $|\eta_T| = 1$ and $T$ is an anti-unitary operator in $H_{\text{LB}}$ with $T^2 = \mathbb{1}$. Using (25,26) one easily gets

$$Tj_x(t, x, i)T^{-1} = -j_x(-t, x, i),$$

$$T\theta_{tx}(t, x, i)T^{-1} = -\theta_{tx}(-t, x, i),$$

(70)

Since $(j_x(t, x, i))_{\text{LB}} \neq 0$ and $(\theta_{tx}(t, x, i))_{\text{LB}} \neq 0$, the overall minus signs in the right hand side of (69,70) imply that $T\Omega_{\text{LB}} \neq \Omega_{\text{LB}}$. Therefore, $T$ generates another state $\Omega_T^{\prime} = T\Omega_{\text{LB}} \in H_{\text{LB}}$ of the system. The entropy fluctuations in this new state are described by

$$w^T_n[S](t_1, x_1, \ldots, t_n, x_n) = \langle \hat{S}(t_1, x_1) \cdots \hat{S}(t_n, x_n) \rangle_T$$

$$\equiv (T\Omega_{\text{LB}}, \hat{S}(t_1, x_1) \cdots \hat{S}(t_n, x_n) T\Omega_{\text{LB}}),$$

(71)

where $(\cdot, \cdot)$ is the scalar product in $H_{\text{LB}}$. Using (69,70) one finds that

$$w^T_{2k-1}[\hat{S}] = -w^T_{2k-1}[\hat{S}],$$

$$w^T_{2k}[\hat{S}] = w^T_{2k}[\hat{S}],$$

(72)

with $k = 1, 2, \ldots$. Therefore, the moments $\mathcal{M}_n^T$ of the probability distribution $\varrho^T(\sigma)$ in the time reversed LB state $\Omega_T^{\prime}$ satisfy

$$\mathcal{M}_{2k-1}^T \leq 0,$$

$$\mathcal{M}_{2k}^T \geq 0,$$

(73)

which is the mathematical consequence of the physical fact that the processes of emission and absorption are inverted with respect to those in $\Omega_{\text{LB}}$.

C. Comment

In the context of particle full counting statistics the possibility to equip the system in Fig. 1 with a measuring devise, representing a kind of galvanometer, has been also considered in the literature [46]-[49]. Following [46], this alternative scenario can be implemented by introducing in (13) the minimal coupling $i\partial_x \rightarrow i\partial_x + A(x)$ with the external field $A(x) \sim \delta(x)$. The physical differences between the two setups have been discussed in detail in [49]. Working out the moments of the entropy production distribution in the presence of a galvanometer, one finds ($k = 1, 2, \ldots$)

$$\mathcal{M}_{2k-1}^T = \tau(\gamma_2 - \gamma_1)^{2k-1} c_1,$$

$$\mathcal{M}_{2k}^T = \tau(\gamma_2 - \gamma_1)^{2k} c_2,$$

(74)

(75)

which differ from (13,14) only by the power of $\tau$. Since $0 \leq \tau \leq 1$ one concludes that $\mathcal{M}_n^T$ satisfy the bound (11) as well.

The function, generating (73,75), is given by

$$\varphi'(\lambda) = 1 + c_1 \tau \sin \{\lambda(\gamma_2 - \gamma_1)\} + c_2 \tau \{\cos \{\lambda(\gamma_2 - \gamma_1)\} - 1\},$$

(76)

and leads to the following probability distribution

$$\varrho'(\sigma) = p'_{12} \delta(\sigma - \sigma'_{12}) + p' \delta(\sigma) + p'_{21} \delta(\sigma - \sigma'_{21}),$$

(77)

with

$$p'_{12} = \frac{\tau}{2}(c_2 - c_1),$$

$$p'_{21} = \frac{\tau}{2}(c_2 + c_1),$$

$$p' = 1 - c_2 \tau,$$

(78)

and

$$\sigma'_{ij} = (\gamma_i - \gamma_j).$$

(79)

One can easily verify that (13) satisfy also in this case (62) and define therefore the relative probabilities controlling the particle emission-absorption processes. This feature provides a nice check on the whole setup with a measuring devise.

In conclusion, the bound (11) is preserved in the presence of a galvanometer as well.

V. OUTLOOK AND CONCLUSIONS

The present paper pursues further the quantum field theory analysis of the physical properties of the LB non-equilibrium steady state. It focuses on the quantum fluctuations of the entropy production in the fermionic system shown in Fig. 1. The junction acts as a non-dissipative converter of heat to chemical potential energy and vice versa. During the energy transmutation, particles are emitted and absorbed by the heat reservoirs, which induces a non-trivial entropy production. Processes with positive, vanishing and negative entropy production occur at the quantum level. In order to characterise the relative impact of these events, we investigate the correlation functions of the entropy production operator in the LB state. The one-point function describes the mean entropy production, whereas the $n$-point functions with $n \geq 2$ capture the relative fluctuations. We discover that in the zero frequency limit these fluctuations generate a true probability distribution, whose moments are all positive. Since the first moment describes the mean entropy production, this remarkable property can be interpreted as a kind of extension of the second principle of thermodynamics to the non-equilibrium quantum fluctuations in the LB state. The search for other non-equilibrium states, which share the same entropy production properties with the LB state, is a challenging open problem.
The results of this paper persists even after introducing a galvanometer in the system and can be generalised in several directions. Along the above lines one can study multi terminal systems as well as the Tomonaga-Luttinger liquid away from equilibrium [69, 70]. The effect of the quantum statistics on the entropy production represents also a deep question, which deserves further study. We are currently investigating this effect in the bosonic version of the fermion system studied above.

Appendix A: Correlation functions in the LB representation

In their original work [32, 33] Landauer and Büttiker derived the two- and four-point correlation functions of \( \{a_i(k), a_i^*(k) : k \geq 0, i = 1, 2\} \) in the LB representation \( \{H_{LB}, \langle \cdot, \cdot \rangle\} \) using quantum mechanical tools. If one is interested in generic \( n \)-point functions, it is more convenient to adopt the formalism of second quantisation developed in [62]. The correlation function [28], needed for the derivation of the entropy production fluctuations, is defined in this formalism by

\[
\langle a_{i_1}(k_1)a_{m_1}(p_1) \cdots a_{i_n}(k_n)a_{m_n}(p_n) \rangle_{LB} = \frac{1}{Z} \text{Tr} \left[ e^{-K} a_{i_1}(k_1)a_{m_1}(p_1) \cdots a_{i_n}(k_n)a_{m_n}(p_n) \right], \quad k_i > 0, p_i > 0,
\]

where

\[
K = \int_0^\infty \frac{dk}{2\pi} \sum_{i=1}^{2} \gamma_i \omega(k) a_{i}(k)a_i(k), \quad Z = \text{Tr} \left( e^{-K} \right).
\]

Referring for the details to [50, 62], we report the final result

\[
\langle a_{i_1}(k_1)a_{m_1}(p_1) \cdots a_{i_n}(k_n)a_{m_n}(p_n) \rangle_{LB} = \begin{vmatrix}
\Delta_{i_1,m_1}(k_1,p_1) & \Delta_{i_1,m_2}(k_1,p_2) & \cdots & \Delta_{i_1,m_n}(k_1,p_n) \\
-\Delta_{i_2,m_1}(k_2,p_1) & \Delta_{i_2,m_2}(k_2,p_2) & \cdots & \Delta_{i_2,m_n}(k_2,p_n) \\
\vdots & \vdots & \ddots & \vdots \\
-\Delta_{i_n,m_1}(k_n,p_1) & -\Delta_{i_n,m_2}(k_n,p_2) & \cdots & \Delta_{i_n,m_n}(k_n,p_n)
\end{vmatrix}.
\]

Here

\[
\Delta_{lm}(k,p) = 2\pi \delta(k-p)\delta_{lm} d_l(\omega(k)),
\]

\[
\bar{\Delta}_{lm}(k,p) = 2\pi \delta(k-p)\delta_{lm} \bar{d}_l(\omega(k)),
\]

where \( d_l(\omega) \) is the Fermi distribution [32] and

\[
\bar{d}_l(\omega) = 1 - d_l(\omega) = \frac{e^{\gamma_l(\omega)}}{1 + e^{\gamma_l(\omega)}}.
\]

Appendix B: Derivation of \( D_n \)

We summarise first the main steps in deriving the integral representation [41]. Using [27] and [A3] one gets a representation of the correlation function \( w_n(S)(t_1, x_1, \ldots, t_n, x_n) \) which involves \( n \) integrations over \( k_i \) and \( n \) integrations over \( p_j \). Then one proceeds as follows:

(i) by means of the delta functions in (A4-A5) one eliminates all \( n \) integrals in \( p_j \);

(ii) plugging the obtained expression in (A9), one performs all \( (n-1) \) integrals in \( t_i \);

(iii) at \( \nu = 0 \) the latter produce \( (n-1) \) delta-functions, which allow to eliminate all the integrals over \( k_i \) except one, for instance that over \( k_1 = k \);

(iv) now the curly bracket factor \( \{ \cdots \} \) in (27) gives the \( x \)-independent expression

\[
\{\chi_{ij}(k;x)\} = -2ik[\delta_{ij}\delta_{ij} - \delta_{ij}(k)\bar{S}_{ij}(k)]^2,
\]

the bar indicating complex conjugation;

(v) finally, in the integral over \( k \) one switches to the variable \( \omega = k^2/2m \).

Following the above steps, one arrives at the integral
representation \((11)\)
with

\[
\mathbb{D}_n = \sum_{i_1, \ldots, i_n=1}^{2} \begin{vmatrix}
T_{i_1 i_1} a_{i_1} & T_{i_1 i_2} a_{i_2} & \cdots & T_{i_1 i_n} a_{i_n} \\
-T_{i_2 i_1} a_{i_1} & T_{i_2 i_2} a_{i_2} & \cdots & T_{i_2 i_n} a_{i_n} \\
\vdots & \vdots & \ddots & \vdots \\
-T_{i_n i_1} a_{i_1} & -T_{i_n i_2} a_{i_2} & \cdots & T_{i_n i_n} a_{i_n}
\end{vmatrix}.
\]  
(B2)

Here and to end of this appendix the \(\omega\)-dependence is omitted for conciseness. The factors \(d_\omega\) is defined in terms of \(S\) by

\[
T_{11} = -T_{22} = |S_{12}|^2 \equiv \tau, \quad T_{12} = \overline{T}_{21} = -S_{11} S_{22}.
\]  
(B3)

In order to compute \(\mathbb{D}_n\) we introduce an auxiliary algebra of fermionic oscillators generated by \(\{a_i, a^*_j : i = 1, 2\}\), which satisfy

\[
[a_i, a^*_j]_+ = \delta_{ij}, \quad [a_i, a^*_j]_+ = [a_i^*, a^*_j]_+ = 0.
\]  
(B5)

Let us consider the quadratic operators

\[
L = \sum_{i=1}^{2} \gamma_i a_i^* a_i, \quad J = \sum_{i, j=1}^{2} a_i^* T_{ij} a_j.
\]  
(B6)

The key observation now is that \(\mathbb{D}_n\) can be represented in the form

\[
\mathbb{D}_n = \frac{\text{Tr} (e^{-L} J^n)}{\text{Tr} (e^{-L})},
\]  
(B7)

which can be verified by explicit computation using \([15, 16]\). One has at this point that

\[
\sum_{n=0}^{\infty} \frac{(in)^n}{n!} \mathbb{D}_n = \frac{\text{Tr} (e^{-L} e^{i\eta J})}{\text{Tr} (e^{-L})}.
\]  
(B8)

The right hand side of (B8) has been previously computed \(^{50}\) for the full counting statistics of the particle current \(^{25}\). Using the result of \(^{50}\), one finds

\[
\sum_{n=0}^{\infty} \frac{(in)^n}{n!} \mathbb{D}_n = 1 + ic_1 \sqrt{\tau} \sin(\sqrt{\tau}) + c_2 \left[ \cos(\sqrt{\tau}) - 1 \right],
\]  
(B9)

were \(c_i\) are defined by \((15)\). From (B9) it follows that

\[
\mathbb{D}_n = \begin{cases} 
1, & n = 0, \\
\tau^k c_1, & n = 2k - 1, \quad k = 1, 2, ..., \\
\tau^k c_2, & n = 2k, \quad k = 1, 2, ...
\end{cases}
\]  
(B10)

implying the result \([14]^{43}\).
