Nomarski imaging interferometry to measure the displacement field of MEMS

Fabien Amiot, Jean Paul Roger

October 23, 2006

Abstract

We propose to use a Nomarski imaging interferometer to measure the out-of-plane displacement field of MEMS. It is shown that the measured optical phase arises both from height and slope gradients. Using four integrating buckets a more efficient approach to unwrap the measured phase is presented, thus making the method well suited for highly curved objects. Slope and height effects are then decoupled by expanding the displacement field on a functions basis, and the inverse transformation is applied to get a displacement field from a measure of the optical phase map change with a mechanical loading. A measurement reproducibility of about 10 pm is achieved, and typical results are shown on a microcantilever under thermal actuation, thereby proving the ability of such a set-up to provide a reliable full-field kinematic measurement without surface modification.

1 Introduction

The increasing interest for micro-electro-mechanical systems (MEMS), especially when they are used as micro-mechanical sensors [1], leads one to focus on the mechanical behavior of micro-objects. First, the standardized mechanical tests at the macro scale have been adapted to the micro one, assuming an homogeneous stress or strain state. Bending [2] and tensile tests [3, 4], as well as fatigue or creep tests [5] are performed since years, providing a global kinematic response of the tested object.

However, classical photolithography processes use visible light to transfer a mask onto a wafer surface. Then, light diffraction limits the achievable
accuracy of the geometric shape of the resulting micro-objects, and the di-
mensions margins tends to increase compared to the dimensions themselves
as the object’s size decreases. The homogeneous stress (or strain) assump-
tion usually satisfied when performing mechanical tests at the macro-scale
is no longer reasonable, and one has to deal with heterogeneous mechanical
tests. As a consequence, one has to perform a spatially resolved kinematic
measurement instead of a global one.

Moreover, as their size decreases, the surface on volume ratio significantly
increases, and the behavior of micro-objects tends to be dominated by surface
effects instead of volume ones. As a consequence, measuring the displacement
field should avoid any surface modification or any contact. In addition, the
surface roughness of MEMS is usually very low, so that measurement tech-
niques involving surface-generated speckle [6] may be difficult to implement
[7].

An optical interferometric imaging set-up is then well suited to measure
displacement fields. The polarization interferometer [8] proposed herein is
derived from the one initially proposed by Nomarski [9]. Dealing with surface
topographies, it has been previously used to determine the mean slope of
tilted samples [10] or to get an image of the roughness of polished surfaces
using a multichannel Nomarski microscope [11, 12, 13].

After recalling the relation between the optical phase induced by the
sample-Wollaston prism group and the measured intensity, the twofold origin
of the optical phase is detailed. A shot-noise limited detection is described,
and the inversion method developed to convert an optical phase change into
an out-of-plane displacement is presented. An example is finally provided
on the measurement of the displacement field of a thermally loaded micro-
cantilever.

2 Measuring a differential topography

2.1 Experimental set-up

The basic interferential microscopy imaging set-up is shown in Fig. 1. A
spatially incoherent light source (LED, \(\lambda = 760\, \text{nm}\)) illuminates a polarization
beam-splitter. The beam reflected by the beam-splitter goes through a polarization modulator and is initially polarized at 45° of the axes of a Wollastons prism. This splits the beam into two orthogonally polarized beams at
a small angle between each other. These beams are focused upon the sample by an objective lens. After reflection and recombination by the Wollaston prism, the beam goes through the polarization modulator and the polarization beam-splitter. The transmitted beam is finally focused on a CCD array. The polarization beam-splitter behaves as crossed linear polarizers mounted at 45° of the axes of the Wollaston prism and of the polarization modulator. One finally gets the interference between two images of the sample, shifted by the Wollaston prism of the distance \( d \). The resulting interference pattern is recorded on a CCD array (DALSA CA-D1, 256 × 256 pixels, 8 bits).

2.2 Interference pattern obtained with a Nomarski imaging interferometer

Let us denote \( \mathbf{p} \) (Fig. 1) the polarisation direction of the beam incident on the Wollaston prism. The Wollaston prism shear-direction is denoted \( \mathbf{y} \). The vector \( \mathbf{a} \) denotes the polarisation direction of the beam impinging on the CCD array. The orthogonal directions, in the prism’s plane, are denoted \( \mathbf{q} \), \( \mathbf{x} \), \( \mathbf{b} \), respectively. One uses a light emitting diode, so that we denote \( E_0 \) the amplitude of the non polarized wave impinging on the polarizing beam-splitter. If \( t_p \) is its amplitude transmission factor, and \( \epsilon_p \) the attenuation factor for the (ideally) suppressed component, the Wollaston prism is illuminated by two orthogonally polarized beams, which electric fields are \( E_{pp}\mathbf{p} \) and \( E_{pq}\mathbf{q} \), with

\[
E_{pp} = E_0 t_p \\
E_{pq} = E_0 \epsilon_p t_p
\]

For a non polarized light source (LED), these two beams are incoherent, and should be treated separately. \( \epsilon_p t_p \) is the transmission factor in the stop direction, so that \( \epsilon_p = 0 \) is the perfect polarizer case. For each beam, the Wollaston prism splits the beam into two orthogonally polarized beams (i.e., a \( \mathbf{x} \) and a \( \mathbf{y} \) component), and the light goes through the path (objective - sample - objective - Wollaston prism). Let us consider that this results in a phase shift \( \phi \) between the \( \mathbf{x} \) and the \( \mathbf{y} \) components. Let us denote \( t_n \) the transmission factor of the path (Wollaston prism - objective - sample - objective - Wollaston prism), \( t_a \) the analyser’s transmission factor, and \( \epsilon_a t_a \) its further attenuation factor in the stop direction. The total intensity \( I \) impinging locally on the CCD array is the sum of the intensity arising from
the two incoherent beams

\[ I = I_p + I_q \]  \hspace{1cm} (3)

Assuming that \((x, p) = (x, b) = \frac{\pi}{4}\), one obtains \[ I = I_0 + A \cos(\phi) \] \hspace{1cm} (4)

\[ I_0 = \frac{|E_0 t_a t_n t_p|^2}{2}(1 + \epsilon_a^2)(1 + \epsilon_p^2) \] \hspace{1cm} (5)

\[ A = \frac{|E_0 t_a t_n t_p|^2}{2}(1 - \epsilon_a^2)(1 - \epsilon_p^2) \] \hspace{1cm} (6)

The contrast of the interference pattern

\[ \frac{A}{I_0} = \frac{(1 - \epsilon_a^2)(1 - \epsilon_p^2)}{(1 + \epsilon_a^2)(1 + \epsilon_p^2)} \] \hspace{1cm} (7)

equals 1 for perfect polarizers \((\epsilon_a = \epsilon_p = 0)\), and decreases when \(\epsilon_a\) or \(\epsilon_p\) increase. Adding an error on the orientation of the polarization beam-splitter leads to the same expression, so that the equation (4) is considered general enough to describe real interference patterns. A typical interference pattern obtained in water with two 70 micrometers long micro-cantilevers and a shear distance \(d \simeq 50 \mu m\) is shown on figure 2. The two sheared images are clearly distinguishable. The optical phase range covers almost 15 interference fringes. The closely packed interference fringes, as well as the quite short correlation length of the used light source (almost 15 \(\mu m\)) reduce the contrast of the interference pattern, thereby limiting the quantitative use of obtained phase map. Let us assume that the optical phase \(\phi\) introduced by the path (Wollaston prism - objective - sample - objective - Wollaston prism) may be decomposed in a term \(\phi_0\) arising from the Wollaston prism and a contribution \(\phi_m\) arising from the object

\[ \phi = \phi_0 + \phi_m \] \hspace{1cm} (8)

The section 2.3 exhibits the phase directly arising from the Wollaston prism, whereas the section 2.4 exhibits the phase arising from the topography of the sample.

### 2.3 Optical phase arising from the Wollaston prism

#### 2.3.1 Optical path functions

Let us consider for simplicity an “ideal” Wollaston prism, which geometry is described in the plane defined by both the optical axis of the system and the
Fig. 3 shows the decomposition of a ray impinging orthogonally on the prism into two emerging rays and the angles definition. Snell-Descartes’ laws at the interface between the two half-prisms read

\[ n_E \sin(\beta_{TM}) = n_o \sin(\theta) \]  
\[ n_o \sin(\beta_{TE}) = n_E \sin(\theta) \]

where \( n_o \) is the ordinary refractive index of the used birefringent material, and \( n_E \) is the extraordinary one. Assuming an ambient media with a refractive index equals to 1, Snell-Descartes’ laws for the exit face of the prism read

\[ \sin(\beta_{TM}^{air}) = n_E \sin(\beta_{TM}^{air} - \theta) \]  
\[ \sin(\beta_{TE}^{air}) = n_o \sin(\beta_{TE}^{air} - \theta) \]

If all the angles are small

\[ \beta_{TM}^{air} - \beta_{TE}^{air} \simeq 2(n_o - n_E)\theta \]

The emerging rays appear to split on a plane, called plane of apparent splitting (PAS), which is here located inside the prism. The use of a modified Wollaston prism \[14\] allows one to move the PAS outside the prism. This plane is considered to be perpendicular to the figure’s plane. Its position is one of the fundamental characteristics of the prism. Investigating the imaging properties of the system, let us denote \( \alpha_1 \) the angle of an impinging ray with respect to the normal of the entrance interface in the figure’s plane. Considering any dependence on \( \alpha_1 \) is then moving in the field of view along the shear direction. The optical path travelled by the \( TE \) (resp. \( TM \)) polarized ray through the prism \( l_{TE}(y, \alpha_1) \) (resp. \( l_{TM}(y, \alpha_1) \)) when the apparent splitting occurs at position \( y \) on the PAS (the origin will be defined later) depends on \( \alpha_1 \). Assuming that all the angles are small,

\[ l_{TE}(y, \alpha_1) \simeq n_E \left( \frac{h}{2} + y\theta \right) + n_o \left( \frac{h}{2} - y\theta \right) + \frac{h \alpha_1 n_1 \theta}{2} \left( \frac{n_o}{n_E} + \frac{n_E}{n_o} \right) \]

\[ l_{TM}(y, \alpha_1) \simeq n_E \left( \frac{h}{2} - y\theta \right) + n_o \left( \frac{h}{2} + y\theta \right) + \frac{h \alpha_1 n_1 \theta}{2} \left( \frac{n_E}{n_o} \left( 2 - \frac{n_E}{n_o} \right) \right) \]

These two functions will be referred as optical path functions.
2.3.2 Optical phase when the PAS matches the objective rear focal plane

Assuming that the PAS of the prism matches the objective rear focal plane, Fig. 4 presents the ray tracing for the two emerging rays of Fig. 3. These two emerging rays intersecting the PAS at the $y_{pas}$ cross the PAS, after reflection on a plane object, at the same point $y_{R,TE} = y_{R,TM}$ when the object is orthogonal to the lens axis. This last point is symmetric of the first with respect to the lens axis. Let us thus define the median plane of the prism $\pi_m$ as orthogonal to both the figure’s plane and the PAS, passing by the $O$ point (see Fig. 3). This point is defined to satisfy the condition $EO = OS$. Let us then consider that the distance between the $\pi_m$ plane and the symmetry axis of the lens is $T_w$. Any point of the PAS may be described either by the abscissa $y$ in the prism’s frame (the origin is at the intersection with $\pi_m$) or by the abscissa $\tilde{y} = y - T_w$ (relative to the symmetry axis of the lens). In the prism’s frame, the rays emerge from the PAS at $y_{pas} = T_w - \tilde{y}$, and the reflected rays go through the PAS at $y_{R,TE} = y_{R,TM} = T_w + \tilde{y}$. The optical paths $l_{ar}^{TE}$ and $l_{ar}^{TM}$ travelled to the sample and back are deduced from $l^{TE}(y, \alpha_1)$ and $l^{TM}(y, \alpha_1)$ and allow one to compute the optical phase

$$
\phi_W^0 = \frac{2\pi}{\lambda} (l_{ar}^{TE} - l_{ar}^{TM}) = \frac{2\pi}{\lambda} \theta \left( 4(n_E - n_o)T_w + h\alpha_1n_1 \left( \frac{n_o}{n_E} + \frac{n_E}{n_o} \left( \frac{n_E}{n_o} - 1 \right) - 1 \right) \right)
$$

(15)

The first term in (15) no longer depends on $y_t$ but on the position of the prism with respect to the symmetry axis of the lens $T_w$, and is homogeneous in the field of view. If the birefringence of the used material is denoted $n_E - n_o = n_o \epsilon$, the additional optical phase difference (second term) proportional to the incidence angle $\alpha_1$ is shown to grow as $\epsilon^2$ whereas the first term scales as $\epsilon$, so that the added optical phase $\phi_W^0$ may be considered homogeneous in the field of view. For a quartz-made Wollaston, $\epsilon \approx 10^{-2}$ so that the added optical phase may be considered homogeneous in the field of view. This is no longer true when the PAS doesn’t match the rear focal plane of the objective, because the reflected rays no longer cross the PAS at the same point (see Fig. 3). Assuming that the PAS remains parallel to the rear focal plane, at a distance $\delta_{PAS}$ and using the same method, the additional optical phase difference $\phi_{PAS}$ is

$$
\phi_{PAS} \approx \frac{8\pi}{\lambda} \theta\alpha_1 \delta_{PAS} (n_E - n_o)
$$

(16)
thus introducing a linear phase along the Wollaston shear direction.

2.4 Optical phase arising from the object topography

2.4.1 Optical phase arising from height variations

The previous ray tracing is shown in the case of a stepped sample (height $\Delta z$) in Fig. 5. Thanks to the Fermat’s principle, tilting the sample doesn’t induce an extra phase shift in the objective-sample path (i.e., regardless of the phase shift induced by the Wollaston prism). The dot line is for the ray reflected under the previous conditions. The optical phase difference $\phi_h$ arising from the step corresponds to a travel along $[AB]$ and $[BC]$, where $C$ is the orthogonal projection of $A$ on $[BD]$. In a medium which refractive index is $n$, this optical phase difference reads

$$\phi_h = \frac{2\pi}{\lambda} n \times (AB + BC) = \frac{4\pi}{\lambda} n \Delta z \cos(\alpha)$$  \hspace{1cm} (17)

where $\alpha$ is the incidence angle on the object. If the numerical aperture of the objective is low enough, $\alpha$ remains small and the above expression expands

$$\phi_h \simeq \frac{4\pi n \Delta z}{\lambda}$$  \hspace{1cm} (18)

As the numerical aperture of the objective increases, the previous expansion is no longer valid and the equation (18) is replaced, for numerical apertures less than 0.3, by

$$\phi_h = \frac{4\pi n \Delta z}{\iota \lambda}$$  \hspace{1cm} (19)

where $\iota$ is a scale parameter depending on the numerical aperture (see appendix A).

2.4.2 Optical phase arising from the local surface orientation

In section D2.4.1, the two orthogonally polarized rays cross on the PAS. This is no longer true if the two rays experience a different surface orientation. Let us denote by $\gamma^{TE}$ (resp. $\gamma^{TM}$) the local surface orientation experienced by the $TE$ (resp. $TM$) ray. For a ray emerging from the PAS at the position $y$ (in the prism’s frame), the reflected rays cross the PAS at the abscissa
\[ y_{R,TE} = \frac{-y + f \tan(2\gamma_{TE})}{1 + \frac{y}{f} \tan(2\gamma_{TE})} \]  
(20)

\[ y_{R,TM} = \frac{-y + f \tan(2\gamma_{TM})}{1 + \frac{y}{f} \tan(2\gamma_{TM})} \]  
(21)

Where \( f \) is the focal length of the objective lens. The optical path travelled by the two rays reads (with \( \alpha_1 = 0 \))

\[ l_{ar}^{TE} \simeq l_{ar}^{TE}(T_w + y, 0) + l_{ar}^{TE}(T_w + y_{R,TE}, 0) \]  
(22)

\[ l_{ar}^{TM} \simeq l_{ar}^{TM}(T_w + y, 0) + l_{ar}^{TM}(T_w + y_{R,TM}, 0) \]  
(23)

and the optical phase difference reads (to the first order with respect to the surface orientation)

\[ \phi_W = \frac{2\pi}{\lambda}(l_{ar}^{TE} - l_{ar}^{TM}) = \frac{4\pi}{\lambda}(n_E - n_o) \tan(\theta) \left(1 + \left(\frac{y}{f}\right)^2\right) f(\gamma_{TE} + \gamma_{TM}) \]  
(24)

One should highlight that this optical phase difference doesn’t arise from the sample itself, but from the optical phase imbalance it introduces when the rays travel back through the Wollaston prism. Moreover, this phase difference depends on the abscissa \( y \), and then on the angle \( \alpha \). It’s also worth noting that a global tilt of the specimen (i.e., \( \gamma_{TE} = \gamma_{TM} \neq 0 \)) induces an extra optical phase. It arises from the previous remarks that the relation between the local surface orientations and the induced optical phase depends on the prism-objective group. This relation may be rewritten

\[ \phi_W = \phi_{ori} + \phi_{tilt} = \frac{\partial \phi_W}{\partial \gamma}(\gamma_{TE} - \gamma_{TM}) + \phi_{tilt} \]  
(25)

with

\[ \phi_{tilt} = \frac{2\partial \phi_W}{\partial \gamma} \gamma_{TM} \]  
(26)

The scalar \( \frac{\partial \phi_W}{\partial \gamma} \) then describes the prism-objective group. It may be obtained when measuring the optical phase when tilting a reasonably flat mirror. The figure 4 shows the result of such a calibration for a quartz Wollaston prism (\( \theta \simeq 18^\circ \)) and a water immersion objective lens (focal length 18mm, NA 0.3,
used to obtain the interference pattern in Fig. 2). The relation is linear, and the fitted slope is

$$2 \frac{\partial \phi_W}{\partial \gamma} = 1.1 \times 10^3$$

(27)

This simple experiment allows one to obtain the sensibility $\frac{\partial \phi_W}{\partial \gamma}$ to a local orientation gap by tilting the whole sample.

Finally, the total measured optical phase difference $\phi$ may be written as the following sum

$$\phi = \phi_{W0}(T_w) + \phi_{PAS}(\delta_{PAS}) + \phi_h(\Delta z) + \phi_W(\gamma_{TE}, \gamma_{TM})$$

(28)

where the two first terms (related to $\phi_0$) account for the path difference introduced by the Wollaston prism itself: an homogeneous term $\phi_{W0}$ and a linear term along the shear direction $\phi_{PAS}$ which vanishes when the PAS matches the rear focal plane of the objective lens. The two last field terms (related to $\phi_m$) originate from the surface topography: height variations $\phi_h$ and slope field, $\phi_W$ including the contribution of the mean tilt of the sample $\phi_{tilt}$ as well as slope variations $\phi_{ori}$.

3 Phase integration, retrieval and unwrapping

3.1 Principle

The optical flux collected by the pixel indexed by $(l, m)$ on the CCD matrix can be formally written according to (4) as

$$I(l, m, t) = I_0 + A \cos[\phi(l, m) + \psi_{mod}(t)],$$

(29)

where $\phi(l, m)$, which is to be determined, is the optical phase introduced by the sample and the Wollaston prism. The phase modulation introduced by the photoelastic modulator reads

$$\psi_{mod}(t) = \psi_0 \sin(2\pi f_{mod} t + \theta_{mod}).$$

(30)

The angles $\psi_0$ et $\theta_{mod}$ are two parameters that can be chosen among many couples. The algorithm to obtain $\phi$ uses four integrating buckets [15]: if $T = 1/f_{mod}$
is the modulation period, four images of the interference pattern can be captured during the period $T$, so that each image results from the integration of the optical flux during a quarter of one period. One obtains four images $E_p$, for $p = 1, 2, 3, 4$

$$E_p = \int_{(p-1)T}^{pT} I(t) dt \quad (31)$$

Combining with Eq. (29) allows one to obtain

$$E_p = \frac{T}{4}(I_0 + AJ_0(\psi) \cos(\phi)) + TA \cos(\phi) \sum_{n=1}^{\infty} \frac{J_{2n}(\psi_0)}{2n} \left[\sin(n p \pi + 2n \theta_{mod}) - \sin(n(p - 1) \pi + 2n \theta_{mod})\right]$$

$$- TA \sin(\phi) \sum_{n=0}^{\infty} \frac{J_{2n+1}(\psi_0)}{2n+1} \times \left(\cos\left(\frac{\pi}{2}(2n+1)(p-1) + (2n+1)\theta_{mod}\right) - \cos\left(\frac{\pi}{2}(2n+1)p + (2n+1)\theta_{mod}\right)\right) \quad (32)$$

where $J_n$ is the first kind Bessel function of $n$ order. The images $E_p$ depend on $I_0$, $\cos(\phi)$ and $\sin(\phi)$, so that using four independent images provides enough information to recover $\phi$. Classical algorithms [15] use particular linear combinations

$$\Sigma_s = -(E_1 - E_2 - E_3 + E_4) = \frac{4TA}{\pi} \Gamma_s \sin(\phi)$$

$$\Sigma_c = -(E_1 - E_2 + E_3 - E_4) = \frac{4TA}{\pi} \Gamma_c \cos(\phi) \quad (33)$$

with

$$\Gamma_s = \sum_{n=0}^{\infty} \frac{(-1)^n J_{2n+1}(\psi_0)}{2n+1} \sin[(2n+1)\theta_{mod}]$$

$$\Gamma_c = \sum_{n=0}^{\infty} \frac{J_{2n+2}(\psi_0)}{2n+1} \sin[2(2n+1)\theta_{mod}] \quad (34)$$

The optical phase is then usually recovered by using an “atan2” function with the arguments provided by the equations (33) with a $(\psi_0, \theta_{mod})$ couple satisfying $\Gamma_s = \Gamma_c$. The indicator

$$\Upsilon^2 = \Sigma_s^2 + \Sigma_c^2 \quad (35)$$

is then independent of the phase $\phi$ and defines the intensity of the signal experiencing the phase $\phi$. As a consequence, the phase obtained from the
previous algorithm is reliable provided that $\Upsilon^2$ is high enough, i.e., if the fringe contrast $\frac{A}{I_0}$ is sufficient. This condition may be difficult to satisfy when the topography is described by a large number of closely packed interference fringes (see Fig. 2). It’s worth noting that the set of four images provides an over-determined set of data. This redundancy is then exploited to provide a more reliable phase measurement.

### 3.2 Least-square phase retrieval

For each pixel of the CCD array, the set of Eq. (32) may be rewritten as a linear system of equations

$$\mathbf{MP} = \mathbf{E}$$

(36)

where the parameters vector $\mathbf{P}$ reads ($\mathbf{\cdot}^t$ denotes the transpose of $\mathbf{\cdot}$)

$$\mathbf{P}^t = \left[ \frac{TI_0}{4}, \frac{TA}{\pi} \cos(\phi), \frac{TA}{\pi} \sin(\phi) \right]$$

(37)

and the images vector

$$\mathbf{E}^t = [E_1, E_2, E_3, E_4]$$

(38)

The matrix $\mathcal{M}$ is built from the modulation parameters

$$\mathcal{M} = \begin{bmatrix}
1 & c(1, \psi_0, \theta_{\text{mod}}) & s(1, \psi_0, \theta_{\text{mod}}) \\
1 & c(2, \psi_0, \theta_{\text{mod}}) & s(2, \psi_0, \theta_{\text{mod}}) \\
1 & c(3, \psi_0, \theta_{\text{mod}}) & s(3, \psi_0, \theta_{\text{mod}}) \\
1 & c(4, \psi_0, \theta_{\text{mod}}) & s(4, \psi_0, \theta_{\text{mod}})
\end{bmatrix}$$

(39)

with

$$c(p, \psi_0, \theta_{\text{mod}}) = \sum_{n=1}^{\infty} \frac{J_{2n}(\psi_0)}{2n} \left[ \sin(n p \pi + 2n\theta_{\text{mod}}) - \sin(n(p-1)\pi + 2n\theta_{\text{mod}}) \right]$$

$$s(p, \psi_0, \theta_{\text{mod}}) = -\sum_{n=0}^{\infty} \frac{J_{2n+1}(\psi_0)}{2n+1}$$

$$\times \left( \cos\left(\frac{\pi}{2}(2n + 1)(p - 1) + (2n + 1)\theta_{\text{mod}}\right) - \cos\left(\frac{\pi}{2}(2n + 1)p + (2n + 1)\theta_{\text{mod}}\right) \right)$$

(41)
The matrix $\mathcal{M}$ is then independent of the considered point. For each pixel of the CCD array, the four images describe the vector $\mathbf{E}$, and the solution parameters vector $\mathbf{P}_{sol}$ is obtained as a minimizer of

$$
\eta^2(\mathbf{P}) = (\mathcal{M}\mathbf{P} - \mathbf{E})^T(\mathcal{M}\mathbf{P} - \mathbf{E}) \tag{42}
$$

and is the solution of the square linear system

$$
\mathcal{M}^T \mathcal{M} \mathbf{P}_{sol} = \mathcal{M}^T \mathbf{E} \tag{43}
$$

The couple $\left(\frac{TA \cos(\phi_{sol})}{\pi}, \frac{TA \sin(\phi_{sol})}{\pi}\right)$ is then extracted, and used as the argument of a standard “atan2” function to provide a less corrupted value of the phase. The figure 8 shows the phase map obtained from the scene presented in Fig. 2 using the least-square algorithm.

### 3.3 Phase unwrapping

The use of the phase integration technique also allows one to reconsider the phase unwrapping problem. In the previous section, the information derived from the experiments is a couple $(X,Y)$ proportional to $(\cos(\phi), \sin(\phi))$

$$(X,Y) = C(\cos(\phi), \sin(\phi)) \tag{44}$$

where $C = \frac{4TA}{\pi} \Gamma_{s,c}$ when the linear combinations (33) are used, and $C = \frac{TA}{\pi}$ when the least-square algorithm is used. In the first case, the couples $(X,Y)$ and $(\Sigma_c, \Sigma_s)$ are equal. For a sake of simplicity, let us consider that a wrapped value of the phase $\phi_p$ is then obtained by using

$$
\phi_p = \text{atan2}(Y, X) \tag{45}
$$

$\phi_p$ lies then in $[-\pi, \pi]$. Recovering the unwrapped value of the phase may turn into a brain-racking task when the phase-map is poorly discretized and the phase jumps are densely packed. Numerous algorithms are available in the literature, based either on local phase unwrapping [16] or on global phase unwrapping [17]. Contrary to most of these algorithms, which use a wrapped phase map as an input, we propose here to use the two fields $X$ and $Y$.

The figure 6 shows a typical case of phase jump between two adjacent points 1 and 2. Their true phase $\phi_1$ and $\phi_2$ is under scrutiny. As $X_1 \approx X_2 \neq 0$ and $Y_1Y_2 < 0$, using the “atan2” function induces a phase jump when moving
from 1 (\( \phi_{p,1} \approx \pi \)) to 2 (\( \phi_{p,2} \approx -\pi \)). Let us then define the frame \((\vec{X}_b, \vec{Y}_b)\), obtained by rotating the \((\vec{X}, \vec{Y})\) frame until the point 1 \((X_1, Y_1)\) belongs to the \((\Omega, \vec{X}_b)\) axis. The phase \(\phi_2 - \phi_1\) of the point 2 in the frame \((\vec{X}_b, \vec{Y}_b)\) is then obtained according to

\[
\tan[\phi_2 - \phi_1] = \frac{-X_2 \sin(\phi_1) + Y_2 \cos(\phi_1)}{X_2 \cos(\phi_1) + Y_2 \sin(\phi_1)}
\]

providing the gap between the true phase values \(\phi_1\) and \(\phi_2\), thus defining (if 1 and 2 are for adjacent pixels), the true phase gradient, modulo \(2\pi\). The couple \((X_2, Y_2)\) is obtained of the four images using one of the two algorithms previously described. \(\cos(\phi_1)\) and \(\sin(\phi_1)\) are deduced from the wrapped value \(\phi_{p,1}\). The phase gradient may then be integrated to provide a true phase map. The figure 11 shows the phase map obtained from the wrapped phase map shown in Fig. 8 using the described phase unwrapping technique.

### 3.4 Reproducibility of the phase measurement

The phase measurement reproducibility is assessed by measuring twice the phase map arising from the same differential topography of a reflective object. One gets two phase fields \(\phi_-(l, m)\) and \(\phi_+(l, m)\). Assuming that each of these fields is the sum of deterministic part \(\phi_d(l, m)\) and of a random part

\[
\phi_-(l, m) = \phi_d(l, m) + b_-(l, m) \quad \text{(47)}
\]

\[
\phi_+(l, m) = \phi_d(l, m) + b_+(l, m) \quad \text{(48)}
\]

the difference between the two phase fields provides then a realization of the difference between two realizations of the noise \(b(l, m)\)

\[
(\phi_+ - \phi_-)(l, m) = (b_+ - b_-)(l, m) \quad \text{(49)}
\]

The figure 11 shows a typical probability density of the variable \((\phi_+ - \phi_-)\) obtained with the set-up described in Section 2.1. The dots are the experimental distribution, whereas the solid line is a least-square fit using a Gaussian, zero-mean, distribution. The agreement is excellent, and allow us to consider \((\phi_+ - \phi_-)\) as a random real number of variance \(2\sigma^2\), if \(b\) is a random variable which variance is \(\sigma^2\). The figure 12 shows the evolution of \(\sqrt{2\sigma^2}\) (converted to heights variation assuming (18)) as a function of the exposure.
time $t_{\text{exp}}$ used to form each intensity image. The experimental variance grows as $t_{\text{exp}}^{-\frac{1}{2}}$, until the exposure time reaches several tens of seconds. The reproducibility is therefore controlled by the exposure time, and the achieved level is (converted to height variations) close to 10 pm.

4 Recovering the displacement field

4.1 Principle

The calculations presented in sections 2.3 and 2.4 allow one to derive an expression for the measured phase $\phi$ as a function of the surface topography. Assuming that the pixel size (in the object plane) is small enough comparing to the object’s size, one proposes for a sake of simplicity to formulate the inversion problem in the object’s plane. Inserting Eq. (19) and Eq. (25) into Eq. (28) allows one to write the total measured phase difference at the point $(x, y)$

$$\phi(x, y) = \phi_0(x, y) + \phi_{\text{tilt}} + \Phi(x, y)$$  \hspace{1cm} (50)

Assuming that the shear direction is parallel to the $y$ axis, and that the local surface orientation $\gamma$ in Eq. (25) is given by the first derivative of the topography, the relation between the measured information $\Phi$ and the topography reads, for a shear distance $d$

$$\Phi(x, y) = \frac{4\pi n}{\lambda \nu} \left( z(x, y + \frac{d}{2}) - z(x, y - \frac{d}{2}) \right) + \frac{\partial \Phi_W}{\partial \gamma} \left( \frac{\partial z}{\partial y}(x, y + \frac{d}{2}) - \frac{\partial z}{\partial y}(x, y - \frac{d}{2}) \right)$$  \hspace{1cm} (51)

where $z(x, y)$ is the topography. To discriminate between the phase arising from the slope variations and those arising from height variations, one proposes to expand the topography on a functions basis

$$z(x, y) = \sum_s \mu_s z_s(x, y)$$  \hspace{1cm} (52)

so that the reference (initial) measured phase field reads

$$\phi_{\text{ref}}(x, y) = \phi_0(x, y) + \phi_{\text{tilt}} + \sum_s \mu_s \Phi_s(x, y)$$  \hspace{1cm} (53)

One should highlight that the shearing amount $d$ is here introduced explicitly to compute the functions basis $\Phi_s(x, y)$ by inserting Eq.(52) into Eq.(51). If
the topography is subjected to an out-of-plane displacement field \( w(x), \phi_{ref} \) is changed into \( \phi_w \) and the new topography is described by

\[
    z(x, y) + w(x, y) = \sum_s (\mu_s + \nu_s) z_s(x, y)
\]

so that the displacement field is also expanded on the same functions basis

\[
    w(x, y) = \sum_s \nu_s z_s(x, y)
\]

The knowledge of the numerical coefficients involved in the definition (51) of \( \Phi(x, y) \) combined with the choice of a functions basis allows one to recover the displacement field by computing the \( \nu_s \) coefficients minimizing

\[
    \eta^2(\nu) = \int \left( \sum_s \nu_s \Phi_s(x, y) - (\phi_w - \phi_{ref})(x, y) \right)^2 dxdy
\]

that is solving the linear system

\[
    \mathbf{N}\nu = \mathbf{F}
\]

with

\[
    N_{si} = \int \Phi_s(x, y)\Phi_i(x, y)dxdy \quad (58)
\]

\[
    F_s = \int \Phi_s(x, y)(\phi_w - \phi_{ref})dxdy \quad (59)
\]

4.2 Example

The micro-cantilevers shown on Fig.2 are placed into a fluid cell, filled with milliQ water which temperature is controlled thanks to a feedback loop controlled Peltier device. These cantilevers are multi-layer cantilevers, made of a silica layer (770 nm), a titanium layer (20 nm) and a gold layer (50 nm). These cantilevers are then subjected to a bimaterial effect, since the coefficient of thermal expansion of the gold layer is almost ten the one of the silica layer. The optical set-up is also used with the Wollaston prism-objective couple calibrated in Section 2.4.2. A reference phase map of the cantilever is captured at 22.6 °C. The temperature is then increased to reach
24.1 °C, and a new phase map is captured. The phase gradients are computed according to the algorithm described in Section 33.3. Recovering the two-dimensional phase map from the phase gradients is an over-constrained problem, so that it is possible to avoid some unreliable data. Reliable data are then located where the indicator defined by Eq.(35) is greater than a user-defined threshold. The figure 13 shows the measured phase map change when the cantilever is submitted to bimaterial effect. One distinguishes the substrate, which is not subjected to any modification. One then remarks the phase change is not homogeneous across the cantilever.

The displacement field is then recovered using the algorithm described in Section 44.1. The function basis is chosen to be able to represent the expected mechanical effects. As a consequence, one chooses cubic hermite polynomials by part along the $y$ direction. In the present example, four elements along the cantilever are found to be sufficient to describe heterogeneous effects, and the projection is made independently for each line across the beam. The figure 14 shows the resulting displacement field, which clearly exhibits an heterogeneous behavior across the cantilever. One should emphasize, that the free end of the cantilever experiences a phase change of 0.8 rad (Fig.13). This value is to be compared to the one arising only from a 12 nm height modification (Fig. 14), which is 0.18 rad (first term in Eq.(51)) ; thus demonstrating the necessity of taking both height and slope changes into account. Moreover, the displacement field shows the cantilever part close to the anchoring rises up as the temperature increases, whereas the cantilever as a whole bends down. This is thought to be the signature of an under-etched cantilever, as the remaining silica pedestal dilates and pushes the surface up. This example typically illustrates the extensive amount of informations provided by full-field measurement compared to pointwise ones.

5 Conclusions

A Nomarski imaging interferometer is used to measure the differential topography of reflective objects. A phase modulation is introduced to measure the phase map arising from the object with a sensitivity independent on the actual phase value. The phase measurement is shown to be shot-noise limited, and a measurement reproducibility of almost 10 pm is achieved. The use of four integrating buckets with a least-square algorithm is shown to improve the phase retrieval in case of low fringe contrast. Moreover, this allows to
reconsider the phase unwrapping problem, so that it is easy to deal with highly curved objects.

The physical origin of the measured optical phase is calculated, and exhibits that the phase difference is due to both height and slope variations. A simple calibration procedure allows one to check for the phase sensitivity to slope variations. These two effects are then decoupled expanding the displacement field onto a chosen functions basis.

The out-of-plane displacement field of a MEMS cantilever subjected to bimaterial effect is then recovered thereby proving the ability of such a set-up to provide a reliable full-field kinematic measurement without surface modification. This tool provides then a full displacement field using a common-path interferometer. Moreover, its stability, as well as its ability to operate through a wide range of media make this set-up a very powerful tool for the study of the mechanical behavior of micro-electro-mechanical systems, providing an extensive amount of reliable information.
A Appendix : Effect of the numerical aperture

The section 22.4 is devoted to the calculation of the optical phase difference arising from the topography of the object under scope. This difference depends on the incidence of the ray on the surface. When using an imaging system, this difference depends therefore on the numerical aperture of the objective lens. The expression (18) was obtained under the assumption that the incidence angle is low enough. To assess this assumption’s validity, let us consider the contribution of each incidence in the figure’s plane to the total intensity in Eq. 4

\[
dI(\alpha) = \left( dI_0 + dA \cos \left[ \frac{4n\pi\Delta z}{\lambda} \cos(\alpha) + \psi \right] \right) d\alpha
\]  

(60)

where \( \psi \) stands for the optical phase independent from the topography. As the fringe spacing depends on the angle \( \alpha \) between the ray and the optic axis, the optical phase arising from the step in Fig. 2 is obtained by weighting and summing the contributions of each rays impinging on the sample at a point of the field of view

\[
I = I_0 + A \frac{2}{\sin^2(\alpha_{max})} \int_0^{\alpha_{max}} \cos \left[ \frac{4n\pi\Delta z}{\lambda} \cos(\alpha) + \psi \right] P(\alpha)^2 \sin(\alpha) d\alpha
\]  

(61)

\( \alpha_{max} \) is related to the numerical aperture of the objective lens \( NA \)

\[
NA = n \sin(\alpha_{max})
\]  

(62)

and to the apodization function \( P(\alpha) \). The choice of this function has been widely discussed [19, 20, 21] and let us the assume

\[
P(\alpha) = (\cos(\alpha))^m
\]  

(63)

where \( m \) is a parameter used to describe the apodization effect. The equation (4) turns into

\[
I = I_0 + A_m F_{NA,m}(\Delta z, \psi)
\]  

(64)

for \( m = 0 \) (Herschel condition),

\[
F_{NA,0}(\Delta z, \psi) \simeq \frac{\sin(k\Delta z(1 - \cos(\alpha_{max})))}{k\Delta z(1 - \cos(\alpha_{max}))} \cos(k\Delta z(1 + \cos(\alpha_{max})) + \psi)
\]  

(65)
where $k = \frac{2\pi}{\lambda}$. If $m \neq 0$, one can derive the Taylor expansion of (64) with respect to $\alpha_{\text{max}}$

$$F_{NA,m}(\Delta z, \psi) = \frac{2}{\sin^2(\alpha_{\text{max}})} \int_0^{\alpha_{\text{max}}} \cos(2k\Delta z \cos(\alpha) + \psi) P(\alpha)^{2m} \sin(\alpha) d\alpha$$

$$\simeq \cos(2k\Delta z + \psi) + \left( \frac{1-2m}{4} \cos(2k\Delta z + \psi) + \frac{1}{2} \sin(2k\Delta z + \psi) k\Delta z \right) \alpha_{\text{max}}^2$$

$$+ \left( \frac{1+4(m^2-m-k^2\Delta z^2)}{24} \cos(2k\Delta z + \psi) \right) \alpha_{\text{max}}^4 + \ldots \quad (66)$$

Let us define the fringe spacing $i_{\text{interf}}$, as the value of $k\Delta z$ where the intensity (64) reaches its first local maximum. As the numerical aperture increases, $i_{\text{interf}} \neq \pi$. Let us thus define the gap

$$\epsilon_{\text{interf}} = 1 - \frac{i_{\text{interf}}}{\pi} \quad (67)$$

Computing $\epsilon_{\text{interf}}$, when the numerical aperture ranges from 0 to 0.6, and $m$ ranges from 0 to 2 shows that $\epsilon_{\text{interf}} < 0$ so that the fringe spacing increases with the numerical aperture (see equation (67)). If the numerical aperture is less than 0.4, $\epsilon_{\text{interf}}$ no longer depends significantly on $m$, so that the numerical aperture value is sufficient to retrieve $\Delta z$ from the intensity value. The above correction of the equation (68) is easy as long as $F_{NA,m}(\Delta z, \psi)$ is pseudo-periodic in a $\Delta z$ range sufficient to describe the topography. This is assessed by defining the ratio

$$r_i = \frac{i_{\text{10}}}{10i_{\text{interf}}} \quad (68)$$

where $i_{\text{10}}$ is the $k\Delta z$ value for which $F_{NA,m}(\Delta z, \psi)$ reaches its tenth local maximum If the numerical aperture is less than 0.3, $r_i$ is 1, thereby proving that $F_{NA,m}(\Delta z, \psi)$ is pseudo-periodic on the defined range. The correction of Eq. (68) then reads

$$\phi_h = \frac{4\pi n\Delta z}{i\lambda} \quad (69)$$

where $i$ depends on the numerical aperture and the apodization function. The figure 15 shows the value of $i$ as a function of both the numerical aperture and $m$. If the numerical aperture is less than 0.3, $i$ no longer depends on $m$, and therefore allows for a direct retrieval of the phase $\phi_h$.
