INTRODUCTION

Biological ageing involves a progressive decline in the ability of an organism to survive stress and disease. It is a complex process which is influenced by both genetic and environmental factors [1]. Common features of ageing include decreased resistance to stress, increased rates of apoptosis, a decline in autophagy and an elevated accumulation of protein aggregates [2]. In humans, ageing correlates with an increased frequency of age-related diseases including heart disease, metabolic syndromes and neurodegenerative diseases such as Alzheimer’s, Parkinson’s and dementia [3].

Prions are aberrant, infectious protein conformations which can self-replicate [4]. They are causally responsible for transmissible spongiform encephalopathies (TSEs) that cause several incurable neurodegenerative diseases in mammals [5]. The underlying cause of TSEs is the structural conversion of a soluble prion protein (PrP\(^C\)) into a prion form (PrP\(^Sc\)) that is amyloidogenic. The amyloid form of the protein can subsequently convert other soluble molecules into the prion form thus resulting in the accumulation of the aberrant proteins in neuronal cells [6, 7]. Human prion diseases are predominantly sporadic constituting approximately 70% of all cases with higher frequencies occurring during advanced age [8]. There are several prion-forming proteins in yeast with the best-characterized being \([PSI^+]\) and \([PIN^+]\), which are formed from the Sup35 and Rnq1 proteins, respectively [9, 10]. \([PSI^+]\) is the altered conformation of the Sup35 protein, which normally functions as a translation termination factor during protein synthesis. The \(de\ novo\) formation of \([PSI^+]\) is enhanced by the presence of the \([PIN^+]\) prion, which is the altered form of the Rnq1 protein whose native protein function is unknown [11].

We have previously shown that autophagy protects against Sup35 aggregation and \(de\ novo\) \([PSI^+]\) prion formation [12]. Autophagy is an intracellular quality control pathway that degrades damaged organelles and protein aggregates via vacuolar/lysosomal degradation [13]. It proceeds in a highly sequential manner leading to the formation of a double-membrane-bound vesicle called the autophagosome. Fusion of the autophagosome with vacuoles/lysosomes introduces acidic hydrolases that degrade the contained proteins and organelles. Autophagy has been implicated in the ageing process and, for example, pharmacological interventions which induce autophagy
result in lifespan extension during yeast chronological ageing [14, 15]. Autophagy appears to play a protective role in the ageing process since dysregulated autophagy is implicated in the accumulation of abnormal proteins associated with several age-related diseases including Alzheimer’s, Parkinson’s and Huntington’s diseases [3, 16, 17].

Yeast cells can survive for prolonged periods of time in culture and have been used as a model of the chronological life span (CLS) of mammals, particularly for tissues composed of non-dividing populations [18]. Additionally, ageing is followed by replicative lifespan, which is defined as the number of budding daughter cells that originates from a particular mother yeast cell before it reaches senescence [19, 20]. Given that amyloidoses are typically diseases of old-age, yeast prions might be expected to form at a higher frequency in aging yeast cells. However, a study using the yeast replicative ageing model found that ageing does not increase the frequency of prion formation [21]. In this current study we have examined [PSI+]+ prion formation using the yeast CLS model and found that the frequency of prion formation is increased during ageing. Furthermore, this frequency is elevated in an autophagy mutant suggesting that autophagy normally acts to suppress age-dependent prion formation. We show that the prion-status of cells influences CLS in an autophagy-dependent manner suggesting that prions can be beneficial in aged populations of yeast cells.

RESULTS
The frequency of de novo [PSI+] formation increases during chronological ageing

We examined yeast CLS to determine whether there is an increased frequency of [PSI+] appearance during ageing. Cultures were grown to stationary phase in liquid SCD media and prion formation measured over time. [PSI+] prion formation was quantified using the ade1-14 mutant allele which confers adenine auxotrophy and prions differentiated from nuclear gene mutations by their irreversible elimination in guanidine hydrochloride (GdnHCl). The frequency of de novo [PSI+] prion formation in a control [PIN+] [psi+] strain grown to stationary phase was estimated to be $1.1 \times 10^5$, comparable to previously reported frequencies [12, 22]. This frequency increased during CLS and a 39-fold increase was observed by day 12 (Fig. 1). We next examined the frequency of [PSI+] prion formation in an atg1 autophagy mutant. Atg1 is a serine/threonine kinase which is responsible for the initiation of autophagy [13, 23]. The frequency of [PSI+] prion formation was further elevated in the atg1 mutant compared with a wild-type strain, suggesting that autophagy normally acts to suppress [PSI+] prion formation during ageing (Fig. 1).

[PSI+] increase longevity in a yeast CLS model

We next examined cell survival to determine whether the [PSI+] prion status of cells influences longevity. For this analysis, flow cytometry was used to monitor propidium iodide uptake to assess yeast cell death [24]. The [PIN+] [PSI+] strain showed a modest increase in maximal lifespan compared with a [PIN+] [psi+] strain (Fig. 2A). Additionally, cell death was lower in the [PIN+] [PSI+] strain over the entire lifespan compared with the [PIN+] [psi+] strain suggesting that the [PSI+] prion improves viability during ageing. To verify this difference in ageing between [PIN+] [PSI+] and [PIN+] [psi+] strains, viability was monitored using colony formation assays. Whilst lifespan measured using the colony forming assay was shorter compared with the propidium iodide uptake assay, it confirmed that the [PSI+] strain maintained viability longer and had an increased lifespan compared with the [psi+] strain (Fig. 2B).

Treatments with GdnHCl block the propagation of most yeast prions by inhibiting the key ATPase activity of Hsp104, a molecular chaperone that is absolutely required for yeast prion propagation [25, 26]. GdnHCl cures yeast cells of [PSI+] and all known prions. Curing the [PIN+] [PSI+] strain with GdnHCl dramatically decreased maximal lifespan to 10 days suggesting that prions are beneficial during CLS (Fig. 2A). It should be noted however, that GdnHCl treatment can also potentially affect Hsp10-related

FIGURE 1: Increased frequency of [PSI+] prion formation during chronological lifespan. [PIN+] [psi+] versions of the wild-type and atg1 mutant stains were grown to stationary phase in SCD media and the frequency of [PSI+] formation measured over time. [PSI+] formation was quantified using the ade1-14 mutant allele by growth on media lacking adenine and differentiated from nuclear mutations by their irreversible elimination in GdnHCl. Data shown are the means of three independent biological repeat experiments expressed as the number of colonies per $10^5$ viable cells. Error bars denote standard deviation. Significance is shown comparing the wild-type and atg1 mutant strains over time (above bars) as well as between the wild-type and atg1 mutant at each time-point (between bars). Statistical analysis was performed by one-way ANOVA: *p < 0.05, **p < 0.01.
processes which are unrelated to prions. Autophagy is known to be required for chronological longevity and for example loss of ATG1 reduces CLS [27]. Similarly, we found that loss of ATG1 reduced CLS in the 74D-694 yeast strain used for our studies (Fig. 2A). Interestingly, longevity was comparable in the [PIN] [PSI'], [PIN'][psi'] and cured strains indicating that active autophagy is required for prion-dependent effects on longevity.

[PSI'] cells have an increased rate of autophagy and decreased concentrations of amorphous protein aggregates

Given that the [PSI']-prion status of cells affects CLS in an autophagy-dependent manner, we examined whether autophagy is altered in [PSI'] cells. We utilized a GFP-Atg8 fusion construct to follow the autophagy-dependent proteolytic liberation of GFP from GFP-Atg8, which is indicative of autophagic flux [28]. In late exponential phase cells (day 1), more free GFP was detected in the [PIN'][PSI'] strain compared with the [PIN'][psi'] and cured [pin][psi'] strains indicative of increased autophagic flux (Fig. 3A). By day three, there was also an increase in autophagic flux in the [PIN'][psi'] and cured [pin][psi'] strains detected as an increase in free GFP. As expected, no autophagic activity was observed for the atg1 knockout mutants. This suggests that cells carrying the [PSI'] prion have increased autophagic activity which may be beneficial during CLS.

We next examined whether the increased autophagic activity in the [PIN'][PSI'] strain affects amorphous protein aggregation, which seemed likely given the previous studies which have suggested that autophagy plays a role in the clearance of misfolded and aggregated proteins [16, 17]. For this analysis, we used a biochemical approach where we grew cells to stationary phase (day 3) and isolated aggregated proteins by differential centrifugation, and removed any contaminating membrane proteins using detergent washes [29]. The levels of protein aggregation were decreased in the [PIN'][PSI'] strain compared with the [PIN'][psi'] and cured [pin][psi'] strains (Fig. 3B). This reduction in protein aggregation required autophagy since the levels of protein aggregation were comparable in the atg1-mutant version strains.

**DISCUSSION**

The majority of prion disease cases in humans occur in a sporadic manner, predominantly manifesting during later stages of life [8]. Similarly, we found an age-dependent increase in the frequency of de novo [PSI'] formation during yeast chronological ageing, with the frequency of spontaneous formation increased approximately 40-fold in aged cells. Yeast has emerged as a powerful model to investigate the stochasticity of the ageing process and its contributing factors. The yeast CLS model more closely resembles the ageing of non-dividing cells such as neurons [18]. Neuronal cells are post-mitotic in nature and rely on proteostasis mechanisms such as autophagy to facilitate the elimination of superfluous and damaged material. The age-dependent increase in the de novo formation of [PSI'] was exacerbated in an atg1 mutant suggesting that autophagy

**FIGURE 2:** Prions improve chronological lifespan. (A) Chronological lifespan analysis, as determined by propidium iodide uptake to assess yeast cell death, is shown for [PIN'][PSI'], [PIN'][psi'] and cured [pin][psi'] versions of wild-type and atg1 mutant strains. Cells were grown in SCD media for 3 days to reach stationary phase and then aliquots taken every 2-3 days for flow cytometry analysis based on propidium iodide uptake by non-viable cells as assayed through flow cytometry. Data shown are the means of at least three independent biological repeat experiments expressed as the percentage of viable cells out of 10000 cells analyzed. Error bars denote standard deviation. (B) Viability measurements are shown for [PIN'][PSI'] and [PIN'][psi'] strains grown under the same conditions as for (A) above. Viability is expressed as a percentage of day zero.
normally acts to suppress spontaneous prion formation during chronological ageing. Similarly, loss of autophagy has been found to cause neurodegenerative diseases in mice [16, 17], supporting a protective role for autophagy in defending against age-associated abnormal protein accumulation and aggregation.

We found that the presence of the \( [PSI'] \) prion confers a beneficial advantage during yeast chronological ageing, which correlates with enhanced autophagic flux. Given that the \( [PSI'] \)-status of cells improves viability during ageing, this may result in selection for \( [PSI'] \) in aged cells. Our data indicate that the presence of the \( [PSI'] \) prion acts to simulate autophagy which results in improved viability during ageing. There is previous evidence to suggest that the increased formation and accumulation of protein aggregates may exert a stimulatory effect on the autophagy pathway. For example, there is a correlation between the accumulation of PrP\(^{Sc} \) and the enhanced activity of quality control pathways including endoplasmic reticulum chaperones, the unfolded protein response and autophagy [30]. In agreement with the idea that enhanced autophagy aids protein homeostasis during ageing, we found reduced levels of amorphous protein aggregation in a \( [PSI'] \) strain, suggesting that autophagy provides a beneficial effect during chronological ageing by removing potentially harmful protein aggregates, including both amorphous and amyloid.

**FIGURE 3: Increased autophagic flux in \( [PSI'] \) strains.** (A) Autophagic flux was monitored in the indicated strains expressing GFP-Atg8 during late exponential (day 1) and stationary phase growth (day 3). Increased free GFP is detected in the \( [PIN'][PSI'] \) strain indicative of autophagic flux. No free GFP is detected in the \( atg1 \) mutant strain which cannot initiate autophagy. Representative images are shown from triplicate experiments with quantification comparing the ratios of free GFP with GFP-Atg8 below. Significance is shown comparing the \( [PIN'][PSI'] \) versions of the wild-type and \( atg1 \) mutant strains with their corresponding \( [PIN'][psi] \) and cured \( [pin] \) versions. Statistical analysis was performed by one-way ANOVA: \(* p < 0.05, ** p < 0.01\). (B) Protein aggregates were isolated from the same strains as shown in panel A at day three of chronological growth and analyzed by SDS-PAGE and silver staining.
forms. Increasing autophagic flux would also presumably act to prevent further amyloid aggregation, potentially protecting against any negative impact of [PSI−] aggregation altering translation termination efficiency.

The [PSI+] prion causes a loss of function phenotype where translation termination activity is reduced due to the aggregation of the normally soluble Sup35 protein [10]. The shift to the [PSI+] prion is thought to allow cells to reprogram gene expression such that new genetic traits become uncovered which may aid survival during altered conditions [31-33]. However, as well as providing a selective advantage through altered gene expression, our data indicate that the [PSI+] prion can improve viability during ageing via modulation of autophagic flux. It is unclear what triggers the increased frequency of [PSI+] prion formation during ageing. One possibility is oxidative stress, since ROS-induced protein aggregation and mitochondrial dysfunction is a common feature in age-related diseases [34, 35]. In addition, ROS and oxidative stress are known to induce yeast and mammalian prion formation [36] which may account for increased [PSI+] formation observed during chronological ageing. Further research will be required to elucidate the exact signaling pathways and the range of quality control mechanisms that may be modulated through the direct and indirect action of the [PSI+] prion during yeast ageing.

MATERIALS AND METHODS

Yeast Strains

[PIN−][PSI−], [PIN−][psi−] and [pin][psi−] derivatives of the wild-type yeast strain 74D-694 (MATa ade1-14 ura3-52 leu2-3,112 trp1-289 his3-200) were used for all experiments. The strain deleted for ATG1 (atg1::HIS3) has been described previously [12].

Growth conditions

Yeast strains were grown at 30°C, 180 rpm in minimal SCD medium (2% w/v glucose, 0.17% yeast nitrogen base without amino acids, supplemented with Kaisser amino acid mixes, Fomedium, Hunstanton, England). Chronological life span experiments were performed in liquid SCD media supplemented with a four-fold excess of uracil, leucine, tryptophan, adenine and histidine to avoid any possible artefacts arising from the auxotropic deficiencies of the strains. Strains were cured by five rounds of growth on YEPD agar plates containing 4 mM GdnHCl.

De novo [PSI+] formation

[PSI+] prion formation was scored by growth in the absence of adenine as described previously [12]. [PSI+] formation was calculated based on the mean of at least three independent biological repeat experiments.
