Abstract

Traditional empirical risk minimization (ERM) for semantic segmentation can disproportionately advantage or disadvantage certain target classes in favor of an (unfair but) improved overall performance. Inspired by the recently introduced tilted ERM (TERM), we propose tilted cross-entropy (TCE) loss and adapt it to the semantic segmentation setting to minimize performance disparity among target classes and promote fairness. Through quantitative and qualitative performance analyses, we demonstrate that the proposed Stochastic TCE for semantic segmentation can efficiently improve the low-performing classes of Cityscapes and ADE20k datasets trained with multi-class cross-entropy (MCCE), and also results in improved overall fairness.

1 Introduction and Related Work

Semantic segmentation is a fundamental problem in computer vision and a pivotal step towards content-based image analysis and scene understanding. It has received an upsurge of attention recently owing to its wide variety of applications in medical imaging [1, 2], autonomous driving [3, 4], satellite image processing [5, 6], and robotics [7, 8], to name a few. Early segmentation methodologies are mostly developed with clustering algorithms at their core [9, 10, 11, 12]. Recent advances in deep learning have revolutionized this field resulting in state-of-the-art (SoTA) image segmentation algorithms such as FCN [13], U-Net [1], PSPNet [14], EncNet [15], Exfuse [16], DeepLabv3+ [17], PS and Panoptic DeepLab [18, 19], HRNet [20] and many other elegant architectures that considerably outperformed the traditional signal processing-based methods.

The choice of loss function is essential for applicability of semantic segmentation in different contexts. Therefore, several studies have investigated the impact of modified loss functions on the performance of semantic segmentation models in generic and use-case related datasets. A comprehensive list of some of these recent loss functions is provided in four different categories in [21]: i) distribution-based losses such as binary class cross-entropy (BCE), ii) region-based losses such as Dice loss [22] and its variants, iii) boundary based losses such as Hausdorff distance [23, 24], and iv) compound losses such Exponential Logarithmic loss [25]. Generic empirical risk minimization (ERM) loss functions such as BCE or Dice can disproportionately advantage or disadvantage some classes in favor of an improved average performance. This results in models that treat certain classes (e.g. with less presence in the training dataset) in an unfair fashion. Somewhat related to this concern, significant research has been conducted on proposing alternatives to the cross-entropy (CE) loss for semantic segmentation to handle imbalanced data using weighted cross entropy [26], balanced cross entropy [27], and the Focal loss [28]. However, none of these approaches directly address the

*Equal contributions.
We then propose a stochastic non-hierarchical batch solution of TCE. In the following, we denote the cardinality of
\( \mathcal{X} \) as \(|\mathcal{X}|\), and the set \( \{1, \cdots, n\} \) as \( [n] \). Let \( \mathcal{D}_t = \{(X, Y)_1, \cdots, (X, Y)_M\} \) be the training dataset containing \( M \) samples with \( X_m \) and \( Y_m \) respectively denoting the \( m \)th image and its corresponding label map (also called mask). Here, \( X \) is of size \( H \times W \times 3 \) for RGB images with a total of \( H \times W = N \) pixels. The corresponding label map \( Y \) is of size \( H \times W \) with elements in \([K]\). \( X_m \) contains a maximum of \( K \) classes each occupying \( n_{m,c} \) pixels, where \( \sum_{c \in [K]} n_{m,c} = H \times W = N, \forall m \). The most commonly used ERM loss for semantic segmentation is the pixel-wise loss \( \mathcal{L} = \sum_{m=1}^{M} \mathrm{CE}(Y_m, \hat{Y}_m) \) \([17, 32, 20]\), which is computed using a multi-class CE between the 1-hot encoded versions of the original label map \( Y \) and the inferred one \( \hat{Y} \):

\[
\mathcal{L} = \frac{1}{MN} \sum_{m=1}^{M} \sum_{c=1}^{K} \sum_{i=1}^{n_{m,c}} y_{m,c,i} \log(\hat{y}_{m,c,i}),
\]

where \( y_{m,c,i} \) denotes the \( i \)th pixel in the \( c \)th class of \( Y_m \). \([31]\) proposes to tilt ERM \( \mathcal{R}(\theta) = 1/M \sum_{i \in [M]} f(x_i, \theta) \) as \( \hat{\mathcal{R}}(\theta, t) = 1/t \log(1/M \sum_{i \in [M]} e^{tf(x_i, \theta)}) \), with loss function \( f(x_i, \theta) \) and model parameters \( \theta \). The tilt parameter \( t \) can be tuned to flexibly promote robustness or fairness. In theory, setting \( t = 0 \) recovers ERM (i.e., \( \hat{\mathcal{R}}(\theta, 0) = \mathcal{R}(\theta) \)), and as \( t \to \infty \), TERM minimizes the worst loss, thus ensuring the model is a reasonable fit for all samples \([31]\). With this in mind, there are (at least) two levels around which a sensible tilting of multi-class CE (MCCE) \((1)\) can be implemented. More specifically, we can tilt \((1)\) at i) image (or sample) level and ii) class level. Let us start with the image level. To tilt at image level, we need to reformulate \((1)\) as

\[
\hat{\mathcal{L}}_{\text{img}} = \frac{1}{t} \log \left( \frac{1}{M} \sum_{m=1}^{M} e^{t \mathcal{L}_m} \right),
\]

where:

\[
\mathcal{L}_m = -\frac{1}{N} \sum_{c=1}^{K} \sum_{i=1}^{n_{m,c}} y_{m,c,i} \log(\hat{y}_{m,c,i}).
\]

Our contributions are as follows: i) We propose to employ tilted cross-entropy (TCE) as a novel loss to promote fairness in semantic segmentation. ii) We adapt the derivations of \([31]\) to fit into semantic segmentation setting and reformulate the commonly used CE loss as TCE. We then propose a stochastic non-hierarchical optimization algorithm for solving TCE. iii) We empirically demonstrate the effectiveness of Stochastic TCE on promoting fairness in semantic segmentation for Cityscapes (and ADE20k in appendix). \footnote{The code will be publicly available soon.}

2 Tilted CE (TCE) for Semantic Segmentation

In this section, we introduce TCE: an adapted and reformulated version of TERM \([31]\) for semantic segmentation. We then propose a stochastic non-hierarchical batch solution of TCE. In the following, we denote the cardinality of \( \mathcal{X} \) as \(|\mathcal{X}|\), and the set \( \{1, \cdots, n\} \) as \( [n] \). Let \( \mathcal{D}_t = \{(X, Y)_1, \cdots, (X, Y)_M\} \) be the training dataset containing \( M \) samples with \( X_m \) and \( Y_m \) respectively denoting the \( m \)th image and its corresponding label map (also called mask). Here, \( X \) is of size \( H \times W \times 3 \) for RGB images with a total of \( H \times W = N \) pixels. The corresponding label map \( Y \) is of size \( H \times W \) with elements in \([K]\). \( X_m \) contains a maximum of \( K \) classes each occupying \( n_{m,c} \) pixels, where \( \sum_{c \in [K]} n_{m,c} = H \times W = N, \forall m \). The most commonly used ERM loss for semantic segmentation is the pixel-wise loss \( \mathcal{L} = \sum_{m=1}^{M} \mathrm{CE}(Y_m, \hat{Y}_m) \) \([17, 32, 20]\), which is computed using a multi-class CE between the 1-hot encoded versions of the original label map \( Y \) and the inferred one \( \hat{Y} \):

\[
\mathcal{L} = \frac{1}{MN} \sum_{m=1}^{M} \sum_{c=1}^{K} \sum_{i=1}^{n_{m,c}} y_{m,c,i} \log(\hat{y}_{m,c,i}),
\]

where \( y_{m,c,i} \) denotes the \( i \)th pixel in the \( c \)th class of \( Y_m \). \([31]\) proposes to tilt ERM \( \mathcal{R}(\theta) = 1/M \sum_{i \in [M]} f(x_i, \theta) \) as \( \hat{\mathcal{R}}(\theta, t) = 1/t \log(1/M \sum_{i \in [M]} e^{tf(x_i, \theta)}) \), with loss function \( f(x_i, \theta) \) and model parameters \( \theta \). The tilt parameter \( t \) can be tuned to flexibly promote robustness or fairness. In theory, setting \( t = 0 \) recovers ERM (i.e., \( \hat{\mathcal{R}}(\theta, 0) = \mathcal{R}(\theta) \)), and as \( t \to \infty \), TERM minimizes the worst loss, thus ensuring the model is a reasonable fit for all samples \([31]\). With this in mind, there are (at least) two levels around which a sensible tilting of multi-class CE (MCCE) \((1)\) can be implemented. More specifically, we can tilt \((1)\) at i) image (or sample) level and ii) class level. Let us start with the image level. To tilt at image level, we need to reformulate \((1)\) as

\[
\hat{\mathcal{L}}_{\text{img}} = \frac{1}{t} \log \left( \frac{1}{M} \sum_{m=1}^{M} e^{t \mathcal{L}_m} \right),
\]

where:

\[
\mathcal{L}_m = -\frac{1}{N} \sum_{c=1}^{K} \sum_{i=1}^{n_{m,c}} y_{m,c,i} \log(\hat{y}_{m,c,i}).
\]
Algorithm 1: Stochastic TCE for Segmentation

Initialize: $w_c = \hat{L}_c = 0, \forall c \in [C]$, $\theta$

Require: $\gamma$, $\eta$, $t$

1. Divide $D^t$ into $D_c^t$, $\forall c \in [C]$

2. while stopping criteria not met do
   3. sample class $c \in [C]$ from a categorical distribution with probabilities $w_c \in W$
   4. sample minibatch $B$ within $D_c^t$
   5. $\hat{L}_B \leftarrow$ compute the loss (1) on $B$
   6. tilt the batch loss: $\tilde{L}_B \leftarrow e^{tL_B}$
   7. $\hat{L}_c \leftarrow (1 - \gamma) \hat{L}_c + \gamma \hat{L}_B$
   8. $w_c \leftarrow \hat{L}_c / (\sum_{l=1}^{K} \hat{L}_l)$, $\forall c \in [C]$
   9. Update model parameters: $\theta \leftarrow \theta - \nabla L_B$

end

Following the same strategy, to tilt at class level per image we need to reformulate (1) as

$$\hat{L}^{cls} = \frac{1}{M} \sum_{m=1}^{M} \frac{1}{t} \log \left( \frac{1}{K} \sum_{c=1}^{K} e^{tL_{m,c}} \right);$$

where: $L_{m,c} = -\frac{1}{n_c} \sum_{i=1}^{n_c} y_{m,c,i} \log(g_{m,c,i})$.

2.1 Solving TCE for Semantic Segmentation

Depending on the tilt level, one has to replace the pixel-wise MCCE part of the semantic segmentation loss with one of the proposed losses in (2) and (3). In our experience, directly plugging these loss functions into semantic segmentation optimization problem could lead to convergence issues and caution has to be put in place. An alternative approach to solve TCE (applicable to both sample and hierarchical levels) is to follow along the stochastic approach proposed in [31]. It is proven in [31] that the gradient of the tilted loss $\hat{L}$ is a weighted average of the gradients of the original individual losses, where each data point is weighted exponentially proportional to the value of its loss. This is the key idea behind the proposed dynamic weight updating and sampling strategy of Stochastic TCE laid out in Algorithm 1. Let us dive deeper and walk through the algorithm. For the sake of simplicity, here we drop the superscript denoting the tilting level of $\hat{L}$ in (2) and (3), and use a subscript to refer to the class $\hat{L}_c$ and batch of data within the class $\hat{L}_B$. The class weights $w_c$ are stored/updated in $W$.

The algorithm starts by dividing the training dataset $D^t$ into $C$ subsets $D_c^t$ each containing the images corresponding to individual classes. Note that an image can contain multiple classes, and thus, these sets can overlap. One can also consider forming non-overlapping sets based on $D^t$. Per propagation round, one class (let us say $c$) will be selected from the categorical distribution $[C]$ with probabilities (weights) $W$ (line 3). These weights are dynamically updated (line 8). Next, a minibatch $B$ is sampled from the training data of the selected class $D_c^t$ and the tilted batch loss $\tilde{L}_B$ is calculated on $B$ (lines 5 and 6). Line 7 proposes a linear dynamic with rate $\gamma$ to update the tilted loss of the selected class $\hat{L}_c$ based on its previous value and the current batch estimate $\tilde{L}_B$. The weight of class $c$, $w_c$, will then be updated using a normalization applied to all the tilted losses (line 8). These dynamically updated weights, $w_c \in W$, will be used in the next iteration to decide from which class to sample. Finally, model parameters in $\theta$ are updated.
### Table 1: Performance comparison on Cityscapes validation set, sorted based on DLv3+ with MCCE.

### 3 Experimental Setup

Here, we assess the impact of TCE on one of the most commonly adopted datasets for semantic segmentation, Cityscapes [4]. The evaluation results for ADE20k [33] can be found in the appendix. Cityscapes contains 2,975 train and 500 validation images from 19 main target classes.

**Training strategy and baselines.** Our trainings are run separately on standard Microsoft Azure 4-GPU P100 Tesla nodes, each with 16GB of memory. For experiments on Cityscapes, we used DeepLabv3+ (also referred to as DLv3+) [17] with ReseNet-101 backbone as our reference implementation of multi-class CE (MCCE), and on top of that we have implemented TCE. DLv3+ is among the top performing model architectures for Cityscapes. Following [17], we used minibatch SGD with learning rate $l_r = 0.01$ and momentum 0.9 for all models, and adjusted for a total minibatch size of 8 (2 per GPU). The reported results of [17] are based on our own trainings, for the sake of a fair comparison. Image crop size and other pre/post-processing parameters are set per default as suggested in [17]. We also compare our performance against the Focal loss for semantic segmentation [28] with the best parameters $\gamma = 2$ and (class weights) $\alpha$ set to the inverse (normalized) class pixel counts computed across the whole dataset.

**Fairness and its evaluation criteria.** The notion of fairness in this setting is promoting a more consistent (and less varied) performance across different classes. This is to ensure that there are less (or ideally no) classes that have been significantly disadvantaged, due to for instance less presence or difficult characteristic features, for the sake of a higher average performance. Promoting fairness by minimizing performance disparity is also a core idea of TERM [31], and resonates with other recent approaches to fairness [29, 34, 35]. More concretely, i) best worst-case performance [29, 35], and ii) least variance across clients/classes [34] are recently proposed to promote/evaluate fairness across a set of tasks or networked clients. We investigate both measures as our key criteria. More specifically, besides the overall mean-intersection-over-union (mIoU), we compare the models on: i) sorted (w.r.t MCCE) bottom and top 25% mIoUs; ii) bottom and top 25th percentiles; and iii) standard deviation and worst case performance (in IoU) across classes. Note that the overall mIoU does not have to be improved when applying TCE; the goal is to minimize performance disparity which can sometimes come at the cost of lower overall mIoU.
Table 3: Fairness criteria for Cityscapes [4]

| Method             | sorted 25%  | (25\textsuperscript{th} perc., mIoU) | overall     |
|--------------------|-------------|--------------------------------------|-------------|
|                    | bottom      | top                                  | worst std.  |
| MCCE [17]          | 56.69       | 94.81                                | (64.60, 57.69) | 48.46 | 14.96 |
| Focal loss [28]    | 63.86       | 93.79                                | (67.64, 60.85) | 49.11 | 13.35 |
| TCE \( t = 0.1 \)  | 63.76       | 94.93                                | (69.22, 62.23) | 49.36 | 13.34 |
| TCE \( t = 1 \)    | 64.29       | 94.66                                | (65.86, 61.29) | 53.47 | 13.57 |

4 Evaluation Results

Table 1 compares the sorted mIoU breakdown of DLv3+ with ResNet-101 backbone [17] trained with the standard multi-class cross-entropy (MCCE) against the same model retrained with the Focal loss and the proposed TCE for \( t = 0.1 \) and 1. Even though we are not necessarily expecting an improvement in the overall mIoU, here for all \( t \)'s, the overall performance with TCE has improved beyond same model trained with MCCE (\( +2\% \) for \( t = 0.1 \) and Focal loss (about \( 1\% \) for \( t = 0.1 \)). TCE with \( t = 1 \) is expected to push more towards minimizing performance disparity and thus promoting fairness (as is also shown in Table 3), and it shows the best improvement in the least performing classes such as “wall” and “train”. The same model architecture, DeepLabv3+ (abbreviated to DLv3+ here), reports better performance results with a more complex backbone Xception-65 [17]. We could not reproduce those results because we did not have access to large enough nodes on Microsoft Azure to accommodate this backbone with batch sizes larger than 8. Nonetheless, we were curious to know how TCE implemented on top of a model with a weaker backbone would compare with the the state-of-the-art (SoTA) results reported in [17]. This comparison is summarized in Tables 2. Interestingly, even compared to the SoTA model with improved backbones, TCE is still improving on several low-performing classes (such as “rider”, “terrain”, “motorcycle”, etc.) in favor of promoting fairness across target classes.

These two tables illustrate promising improvement in low-performing classes the extent of which is further investigated and is summarized in Table 3. Here, the following three measures are presented. First, the sorted bottom and top 25\% mIoU. To compute this, the target classes are sorted based on the IoU performance breakdown of the the model trained with MCCE. Then for each model the mIoU of the bottom and top 25\% (5 classes out of 19) are taken into account. This is to demonstrate the impact of TCE compared to the reference MCCE. Here, improved mIoU for bottom classes (even at cost the of lower mIoU for the top ones) indicates more fairness. Second, in a tuple, the IoU threshold corresponding to (bottom and top) 25th percentile of each model and the mIoU of the classes falling within the percentile are presented.
Note that in this case each model will be sorted according to its own target class IoU’s. The idea is that improvement in bottom percentile threshold and corresponding mIoU could be indicative of improved fairness. Again, we do not expect improvement but potential drop in the top percentiles; they are reported to provide a more complete picture. Third, the overall fairness measures [29, 34, 35], i.e., the worst performance among target classes and the standard deviation across class IoU’s (denoted respectively as worst and std. in the table) are presented.

The results show that on all three metrics TCE offers improved fairness when compared to MCCE and Focal loss. Let us focus on \( t = 1 \). In sorted bottom 25%, we gain +6% and +0.4% beyond MCCE and Focal loss, respectively. For 25th percentiles, +5% and +0.4% beyond MCCE and Focal loss, respectively. The TCE with \( t = 0.1 \) seems to do better (+1% beyond Focal) which could be due to different sorting per model, and thus, different classes falling in those percentiles. In the overall metrics [29, 34, 35], the worst-case IoU (among target classes) is 5% and +4% better (higher) than MCCE and Focal loss, respectively. The standard deviation across classes is improved (decreased) by +1% compared to MCCE and remains in the same regime as Focal loss. Finally, qualitative results in Fig. 1 further corroborate the impact of TCE in comparison with MCCE and Focal loss. The top two rows highlight improvement in “rider”, “bus”, and “truck”, and the next two rows show improvement in “tram” and “sidewalk”, most of which associate to the low-performing classes of the model trained with MCCE. There is plenty of room for extending this work. An avenue to explore is different implementations of TCE, especially (in a non-stochastic fashion) by directly plugging in (2) and (3) as the optimization loss function. In doing so, remedies have to be put in place to circumvent convergence issues. Further quantitative and qualitative results on ADE20k dataset are provided in the appendix. More experimentation on other datasets is left as future work.

5 Acknowledgment

The authors would like to thanks Shell Global Solutions International B.V. and Delft University of Technology (TU Delft) for their support and for the permission to publish this work. The authors extend their appreciation to Ahmad Beirami from Facebook AI for helpful discussions on tilted empirical risk minimization (TERM).

A  More Evaluation Results

Table 4: Performance comparison on ADE20k validation set, bottom 22 classes of MCCE.

| Method | land | lake | shower | blanket | step | hill | bag | eav scrn. | tray | stage | hovel | dirt | track |
|--------|------|------|--------|---------|------|------|-----|-----------|------|-------|-------|------|-------|
| MCCE [32] | 0.00 | 1.96 | 2.62 | 2.95 | 5.47 | 5.52 | 5.81 | 6.12 | 6.94 | 7.66 | 8.77 | 10.37 |
| TCE \( t = 1 \) | 3.58 | 34.94 | 1.44 | 7.13 | 5.74 | 3.46 | 6.04 | 8.50 | 5.58 | 6.82 | 9.14 | 1.71 |
| TCE \( t = 1 \) | 1.08 | 14.64 | 2.30 | 4.60 | 3.19 | 4.76 | 6.19 | 0.86 | 9.18 | 7.37 | 8.49 | 2.04 |

Table 5: Performance comparison on ADE20k validation set, top 22 classes of MCCE.

| Method | sky | p. table | bed | toilet | road | ceiling | car | building | tent | bus | floor | person |
|--------|-----|----------|-----|--------|------|---------|-----|----------|------|-----|-------|---------|
| MCCE [32] | 93.92 | 91.99 | 86.39 | 83.02 | 82.70 | 81.76 | 81.66 | 81.41 | 80.50 | 79.12 | 78.91 | 78.42 |
| TCE \( t = 1 \) | 10.71 | 11.55 | 11.62 | 12.63 | 12.67 | 17.68 | 18.57 | 19.37 | 19.48 | 9.51 | 43.87 |
| TCE \( t = 1 \) | 12.85 | 12.27 | 9.37 | 12.83 | 18.92 | 30.93 | 10.58 | 16.53 | 19.98 | 11.56 | 41.32 |
| TCE \( t = 1 \) | 17.17 | 10.49 | 12.78 | 10.51 | 13.34 | 15.87 | 45.20 | 17.36 | 19.61 | 18.74 | 11.17 | 41.77 |

Table 6: Fairness criteria for ADE20k [33].

| Method | sorted 15% | (15\(^{th}\) perc., \text{mIoU}) | overall | worst std. |
|--------|------------|---------------------------------|---------|------------|
| MCCE [17] | 9.51 | 78.20 | (19.55, \text{mIoU}) | (69.14, 78.20) | 0.0 | 21.95 |
| TCE \( t = 1 \) | 11.56 | 77.25 | (15.31, 8.04) | (67.95, 77.62) | 1.44 | 22.39 |
| TCE \( t = 1 \) | 11.17 | 78.17 | (15.67, 7.99) | (67.26, 78.49) | 0.86 | 22.79 |

We further assessed the impact of the proposed tilted cross-entropy (TCE) on yet another commonly adopted datasets for semantic segmentation; i.e., ADE20k [33]. ADE20k contains 20,100 images for training and 2,000 for validations from 150 object and stuff classes. As such, compared to Cityscapes [4], the typical scenes in ADE20k can be more complex in that they can potentially contain more target classes per image. For experiments on ADE20k, we have used the UPerNet [32] with ResNet-101 backbone as our reference implementation of multi-class cross-entropy (MCCE) and on top that we have implemented the proposed TCE. UPerNet is among the top performing model architectures for ADE20k. Following [32], we used minibatch SGD with learning rate \( t_r = 0.01 \) and momentum 0.9 for all models, and adjusted for a total minibatch size of 8. The reported results of [32] are based on our own trainings, for the sake of a fair comparison. Image crop size and other pre/post-processing parameters are set per default as suggested in [32]. Our evaluation strategy is exactly the same as explained for Cityspaces in Section 3 except that here we consider sorted 15\% (bottom and top 22 classes) and bottom and top 15\%th percentile. This is because ADE20k contains much larger number of classes compared to Cityscapes (150 vs 19).

Table 4, compares the sorted mIoU breakdown of MCCE (UperNet [32]) for its bottom 15\% (22) classes against the same model trained with TCE. Here, again we see improvement in the low-performing classes, which is also reflected in the mIoU of these 22 classes (for both \( t = 0.1 \) and 1). Conversely, the overall mIoU (denoted as mIoU(all)) has dropped for ADE20k irrespective of the choice of the tilting parameter \( t \). To reiterate, TCE favors a less varied (and more fair) performance across classes, and not an improved overall mIoU. Table 5 provides the top part. As can be seen, here for most classes, MCCE outperforms TCE which confirms that the improvement in bottom (low-performing) classes is coming at the cost of performance degradation in top performing classes. The complete MIoU breakdown of ADE20k with 150 classes would not fit in two tables. Instead Table 6 summarizes the fairness measures for ADE20k. Here, the trend is less consistent compared to Cityscapes. TCE shows improvement in sorted percentage and overall fairness.
measures, but in percentile analysis this is not visible. This could be because typical ADE20k images contain more target classes. As such, in Algorithm 1, every time we samples from $D^c_t$ to improve class $c$, we also involve several other classes. A possible remedy could be to tilt at class level per image. Finally, Figure 2 provides further qualitative examples illustrating the impact of TCE on ADE20k dataset. From the top row to bottom, TCE is providing a more consistent label map compared to MCCE for “lake”, “truck”, “blanket”, “fountain” and “step” all which lie within the low-performing bottom 15% (22) classes of ADE20k.
