ABSTRACT

We present spectroscopy of the eclipsing recurrent nova U Sco. The radial velocity semi-amplitude of the primary star was found to be \( K_W = 93 \pm 10 \) km s\(^{-1}\) from the motion of the wings of the HeII \( \lambda 4686 \) Å emission line. By detecting weak absorption features from the secondary star, we find its radial velocity semi-amplitude to be \( K_R = 170 \pm 10 \) km s\(^{-1}\). From these parameters, we obtain a mass of \( M_1 = 1.55 \pm 0.24 \) M\(_{\odot}\) for the white dwarf primary star and a mass of \( M_2 = 0.88 \pm 0.17 \) M\(_{\odot}\) for the secondary star. The radius of the secondary is calculated to be \( R_2 = 2.1 \pm 0.2 \) R\(_{\odot}\), confirming that it is evolved. The inclination of the system is calculated to be \( i = 82.7^\circ \pm 2.9^\circ\), consistent with the deep eclipse seen in the lightcurves. The helium emission lines are double-peaked, with the blue-shifted regions of the disc being eclipsed prior to the red-shifted regions, clearly indicating the presence of an accretion disc. The high mass of the white dwarf is consistent with the thermonuclear runaway model of recurrent nova outbursts, and confirms that U Sco is the best Type Ia supernova progenitor currently known. We predict that U Sco is likely to explode within \( \sim 700 \) 000 years.

Key words: accretion, accretion discs – binaries: eclipsing – binaries: spectroscopic – stars: individual: U Sco – novae, cataclysmic variables.

1 INTRODUCTION

U Sco belongs to a small class of cataclysmic variables (CVs) known as recurrent novae (RNe), which show repeated nova outbursts on timescales of decades. Of these, U Sco has the shortest recurrence period (\( \sim 8 \) y), with recorded outbursts in 1863, 1906, 1936, 1979, 1987 and 1999. It is likely that others have been missed due to its proximity to the ecliptic (4\(^\circ\)).

The RN class is further divided into three groups, depending on the nature of the secondary star (red giant, subgiant or dwarf), each of which have different eruption mechanisms (see Warner 1995 & Webbink et al. 1987 for reviews). U Sco is the only object of the three in the sub-giant class which eclipses (Schaefer 1990), and also shows evidence of secondary absorption lines (Hanes 1985), making it the best candidate for the determination of system parameters.

The outburst mechanism for the U Sco sub-class of RNe is believed to be a modified version of the thermonuclear runaway (TNR) model of classical novae outbursts (e.g. Starrfield, Sparks & Truran 1985). In this model, the primary star builds up a layer of material, accreted from the secondary star, on its surface. The temperature and density at the base of the layer become sufficiently high for nuclear reactions to begin. After ignition, the temperature rises rapidly and the reaction rates run away, until the radiation pressure becomes high enough to eject most of the accreted material. This process occurs when the accreted layer reaches a critical mass (Truran & Livio 1986), the value of which is a strongly decreasing function of the white dwarf mass. Therefore, to reduce the time interval between eruptions to those observed in the RNe, either the mass accretion rate (\( \dot{M} \)) or the white dwarf mass must be increased. For RNe, the white dwarf mass is the more important constraint because there is an upper limit to \( \dot{M} \) above which the degeneracy on the surface of the white dwarf weakens, and no powerful eruption can occur. For this model to account for the short times between outbursts as seen in RNe, the white dwarf must have a mass close to the Chandrasekhar limit. A tight constraint on the white dwarf mass in U Sco...
is hence theoretically important, as it will provide a direct observational test of the TNR model for this group of RNe.

The mass of the white dwarf in U Sco is also important in terms of binary evolution and the role of RNe as Type Ia supernova progenitors. Livio & Truran (1994) suggested, on the basis of the abundance determinations of the ejecta of RNe, that the mass of the envelope ejected during the outburst might be smaller than the amount of accreted material. In the case of high mass white dwarf systems, the primary could be pushed over the Chandrasekhar limit to produce a supernova explosion. A tight constraint on the white dwarf mass and the mass accretion rate allows the time to supernova to be calculated, which according to Stark, Sparks & Shaviv (1988), could be as little as 50,000 years.

There have been two previous attempts to measure the mass of the white dwarf in U Sco. Johnston & Kulkarni (1992) attempted to use low resolution spectra to determine the radial velocity semi-amplitude of both components by looking at the emission and absorption line shifts. They calculated a white dwarf mass of 0.23–0.60\(M_\odot\), a result disputed by Duerbeck et al. (1993), who obtained 10 spectra with poor phase coverage, but were able to conclude a high primary mass, although their errors were large (\(M_1 = 1.16 \pm 0.69M_\odot\)). Schaefer & Ringwald (1995) rephased the radial velocity measurements of Johnston & Kulkarni (1992) and Duerbeck et al. (1993) using a new orbital period. They concluded that due to inconsistent \(\gamma\) velocities, a phase shift in the emission lines and a large scatter in the radial velocity curves, no reliable white dwarf mass could be derived from the data.

In addition to this, Hachisu et al. (2000a) successfully modelled the quiescent light curve of U Sco with a white dwarf mass of \(M_1 \sim 1.37M_\odot\), a secondary mass of \(M_2 = 0.8\text{–}2.0M_\odot\) and an orbital inclination of \(\sim 80^\circ\). Indirect support that the TNR model is the outburst mechanism in U Sco has also been found by the observation of luminous supersoft X-ray emission after the 1999 outburst (Kahabka et al. 1999). They also constrain the white dwarf to be massive from the temperature of the optically thick supersoft component. In this paper, we present new measurements of the radial velocity semi-amplitude of the primary and secondary stars in U Sco and hence a new determination of the mass of the white dwarf in this system.

2 OBSERVATIONS

On the nights of 1999 April 15–19 we obtained 51 spectra of the recurrent nova U Sco with the 3.9m Anglo-Australian Telescope (AAT) in Siding Springs, Australia. We covered one complete orbit of U Sco during this time, including an eclipse – a full journal of observations is given in Table 1. The exposures were all 1500 s with about 50 s dead-time for one complete orbit of U Sco during this time, including an eclipse. The exposures were all 1500 s with about 50 s dead-time.

The open circle represents a measurement with an unrecorded error.

Table 1. Journal of observations for U Sco. Orbital phase is calculated using the new ephemeris presented in this paper (equation 1).

| UT Date | UT start | UT end | No. of spectra | Phase start | Phase end |
|---------|----------|--------|----------------|-------------|-----------|
| 1999 April 15 | 14:57 | 19:09 | 8 | 0.31 | 0.44 |
| 1999 April 16 | 14:14 | 19:21 | 11 | 0.09 | 0.26 |
| 1999 April 17 | 14:21 | 19:11 | 10 | 0.92 | 1.07 |
| 1999 April 18 | 14:20 | 19:16 | 11 | 0.72 | 0.88 |
| 1999 April 19 | 14:23 | 19:30 | 11 | 0.54 | 0.70 |

in order to correct for slit losses. Arc spectra were taken between every U Sco exposure to calibrate instrumental flexure. The nights were all photometric, and the seeing varied between approximately 1.0 arcsec and 1.8 arcsec throughout the five nights.

U Sco underwent its sixth recorded outburst on 1999 February 25, reaching a maximum brightness of \(V = 7.6\) (Schmeer et al. 1999). The observations recorded in this paper were taken approximately 49 days after outburst maximum, as can be seen from the lightcurve in Fig. 1, by which time the magnitude had decreased to approximately one magnitude above its quiescent level. Unfortunately, the single data point in Fig. 1 corresponding to the dates of our observations has no recorded uncertainty. It is therefore impossible to conclude whether we actually observed U Sco during an anomalously high state. What is certain, however, is that the additional shot noise in the continuum made it more difficult than we expected to detect absorption lines from the secondary star. The total flux in each spectrum is plotted in Fig. 2 as a function of Heliocentric Julian Date (HJD) following equation (1) (see Section 3). The eclipse occurs on the third night of observation. There is also some evidence for a slight downward trend in brightness over the five nights.

3 DATA REDUCTION

We debiased the data and corrected for the pixel-to-pixel variations with a tungsten lamp flat-field. The sky was subtracted by fitting second-order polynomials in the spatial direction to the sky regions on either side of the object spectra. The data were then optimally extracted (Horne 1986) to give raw spectra of U Sco and the comparison star. Arc spectra were then extracted from the same locations on the detector as the targets. The wavelength scale for each spectrum was interpolated from the wavelength scales of two neighbouring arc spectra. The root-mean-square error in the fourth-order polynomial fits to the arc lines was $\sim 0.025\AA$.

The next stage of the reduction process was to correct for the instrumental response and slit losses in order to obtain absolute fluxes. A third-order spline fit to the continuum of the spectrophotometric standard star was used to remove the large-scale variations of instrumental response with wavelength. The slit-loss correction was performed by dividing the U Sco spectra by spline fits to the comparison star spectra, and then multiplying the resulting spectra by a spline fit to a wide-slit comparison star spectrum.

4 RESULTS

4.1 Ephemeris

The times of mid-eclipse were determined by fitting a parabola to the eclipse minimum (the solid curve in Fig. 2). A least-squares fit to the 9 eclipse timings found in Schaefer & Ringwald (1995) and our eclipse yields the following ephemeris:

$$T_{\text{mid-eclipse}} = \text{HJD} 2 447 717.6145 + 1.230 5522 E$$

$$\pm 0.0044 \pm 0.000 0024$$

The differences between the observed and calculated times of mid-eclipse are given in Table 2. We find no evidence for a non-zero value for $P$, in agreement with Schaefer & Ringwald (1995).

4.2 Average Spectrum

The average spectrum of U Sco is displayed in Fig. 3, and in Table 3 we list fluxes, equivalent widths and velocity widths of the most prominent lines measured from the average spectrum.

The spectrum is dominated by single-peaked emission lines between $\lambda\lambda 4870$–5080$\AA$ originating from the recent outburst. The identification of these nebular lines is complicated by their large widths, but the blend is likely to have contributions from NII, NIII, NV, OIII and OV, indicating a very high degree of excitation. Both Sekiguchi et al. (1988) and Munari et al. (1999) attribute the complex around $\lambda 5015\AA$ to a blend of He I and NII in the 1987 and 1999 outbursts, respectively. Barlow et al. (1981) suggest in the 1979 outburst the presence of H$\beta$ at $\lambda 4861\AA$, and strong OII emission at $\lambda\lambda 4959/5007\AA$. This is supported by comparison with nebulae around classical novae such as Nova Cygni 1992 (Moro-Martín, Garnavich & Noriega-Crespo 2001). There is also evidence of CIV emission at $\lambda 1558\AA$, in agreement with the 1987 outburst (Sekiguchi et al. 1988). The other strong features in the blend are likely to be due to NIII and NV, in agreement with Barlow et al. (1981), and optical spectra of Nova GQ Muscae 1983 (Péquignot et al. 1993). It is difficult to directly compare our spectra to the spectra of the 1979 outburst (Barlow et al. 1981) and the 1987 outburst (Sekiguchi et al. 1988) because the latter two datasets were taken much closer to the eruption.

U Sco also shows strong, broad, double-peaked He II lines at $\lambda\lambda 4686\AA$ and $\lambda 5412\AA$, typical of emission from an accretion disc in a high inclination system (e.g. Horne & Marsh 1984).

The secondary star features cannot clearly be seen in Fig. 3 as the spectra have been averaged without being corrected for orbital motion. Consequently, any faint absorption lines will have been smeared out.

However, when the orbital motion of the secondary star is removed, the MgII triplet ($\lambda\lambda 5167,5173,5184\AA$) can clearly be identified (see Section 4.7 and Figure 4).
4.3 Light Curves

The continuum light curve for U Sco was computed by summing the flux in the wavelength range $\lambda\lambda5080–5390\,\AA$, which is devoid of emission lines. A polynomial fit to the continuum was then subtracted from the spectra and the emission line light curves were computed by summing the residual flux after continuum subtraction.

The resulting light curves are plotted in Fig. 4 as a function of phase, following our new ephemeris. The continuum shows a symmetrical eclipse, with flickering throughout. There appears to be a dip in magnitude around phase 0.5, perhaps indicative of a secondary eclipse, but there are too few data points to be conclusive. In addition, as a consequence of U Sco’s long orbital period (1.23 days), the lightcurves represent data from five nights. Therefore, not all of the variability can be necessarily attributed to orbital effects.

The eclipses of the HeII lines have a different shape from the continuum. Both lightcurves show a long egress, and a pre-eclipse increase in brightness. There is no evidence for significant variability in the lightcurve of the nebular lines ($\lambda\lambda4870–5080\,\AA$), supporting the idea that the lines are produced in a region external to the orbits of the stellar components.

4.4 Trailed spectrum

We subtracted polynomial fits to the continua from the spectra and then rebinned the spectra onto a constant velocity-interval scale centred on the rest wavelength of the lines. The rest wavelength of the nebular lines was taken as $\lambda4975\,\AA$. The data were then phase binned into 40 bins, 36 of which were filled. Fig. 5 shows the trailed spectra of the HeII $\lambda4686\,\AA$, HeII $\lambda5412\,\AA$ and nebular lines in U Sco.

The HeII lines show two peaks, which vary sinusoidally with phase. This, and the rotational disturbance (where the

| Line          | Flux $\times 10^{-14}$ ergs cm$^{-2}$ s$^{-1}$ | EW $\AA$ | FWHM km s$^{-1}$ | FWZI km s$^{-1}$ |
|---------------|-----------------------------------------------|----------|------------------|------------------|
| HeII $\lambda4686\,\AA$ | 1.345 ± 0.007 | 6.98 ± 0.04 | 700 ± 50 | 1600 ± 100 |
| HeII $\lambda5412\,\AA$ | 0.177 ± 0.005 | 1.18 ± 0.03 | 700 ± 100 | 1500 ± 300 |
| Blend         | 11.95 ± 0.02   | 82.9 ± 0.1  |                  |                  |

Figure 3. The average spectrum of U Sco, uncorrected for orbital motion.
blue-shifted peak is eclipsed before the red-shifted peak) is evidence for origin in a high inclination accretion disc. There is also some evidence for an emission component moving from blue to red between phases 0.6 – 0.9.

4.5 Doppler Tomography

Doppler tomography is an indirect imaging technique which can be used to determine the velocity-space distribution of line emission in cataclysmic variables. For a detailed review of Doppler tomography, see Marsh (2000).

Fig. 4 shows the Doppler map of the HeII $\lambda 4686$ Å line in U Sco, computed from the trailed spectra of Fig. 3 but with the eclipse spectra removed. The data for the HeII $\lambda 5412$ Å line were too noisy to produce a Doppler map. The three crosses on the Doppler map represent the centre of mass of the secondary star (upper cross), the centre of mass of the system (middle cross) and the centre of mass of the white dwarf (lower cross). These crosses, the Roche lobe of the secondary star, and the predicted trajectory of the gas stream have been plotted using the radial velocities of the primary and secondary stars, $K_W = 93 \pm 10$ km s$^{-1}$ and
Figure 5. Trailed spectra of HeII λ4686 Å, the nebular lines and HeII λ5412 Å. The second panel from the left shows the HeII λ4686 Å line computed from the Doppler map. The gaps around phases 0 and 1 in the computed data correspond to eclipse data, which were omitted from the fit; the gaps around phases 0.3, 0.5, 1.3 and 1.5 are due to missing data. The data only cover one cycle, but are folded over for clarity.

K_R = 170 ± 10 km s^{-1}, derived in Section 4.9. The series of circles along the gas stream mark the distance from the white dwarf at intervals of 0.1L_1, ranging from 1.0L_1 at the red star to 0.3L_1.

A ring-like emission distribution, characteristic of a Keplerian accretion disc centred on the white dwarf, is clearly seen in Fig. 6. There is some evidence for an increase in emission downstream from where the computed gas stream joins the accretion disc, implying the presence of a bright spot. This kind of behaviour has been seen in other CVs – e.g. WZ Sge (Spruit & Rutten 1998).

4.6 Radial velocity of the white dwarf
The continuum-subtracted data were binned onto a constant velocity interval scale about each of the two helium line rest wavelengths. In order to measure the velocities, we used the double-Gaussian method of Schneider & Young (1980) since this technique is sensitive mainly to the motion of the line wings and should therefore reflect the motion of the white dwarf with the highest reliability. We varied the Gaussian widths between 150–300 km s^{-1} at 50 km s^{-1} intervals, as well as varying their separation a from 200–1500 km s^{-1}. We then fitted

V = γ - K \sin[2\pi(\phi - \phi_0)]

(2)
to each set of measurements, omitting the 9 points around primary eclipse which were affected by the rotational disturbance. An example of a radial velocity curve obtained for the HeII λ4686Å line for a Gaussian width of 300 km s^{-1} and separation 1000 km s^{-1} is shown in Fig. 7. The data for the HeII λ5412Å line were too noisy to determine accurate radial velocities.

The radial velocity curve has a negligible phase offset, an indication that the helium line is a reliable representation of the motion of the white dwarf. The results of the radial velocity analysis are displayed in the form of a diagnostic
Figure 6. Doppler map of HeII λ4686Å emission in U Sco.

By plotting $K$, its associated fractional error $\sigma_K/K$, $\gamma$ and $\phi_0$ as functions of the Gaussian separation, it is possible to select the value of $K$ that most closely represents the actual $K_W$ (Shafer, Szkody & Thorstensen 1986). If the emission were disc dominated, one would expect the solution for $K$ to asymptotically reach $K_W$ when the Gaussian separation becomes sufficiently large, and furthermore, one would expect $\phi_0$ to fall to 0. This is seen to occur at a separation of $\sim 1200$ km s$^{-1}$, corresponding to $K_W \sim 93$ km s$^{-1}$. There is, however, no sudden increase in $\sigma_K/K$, prompting us to employ a different approach.

Marsh (1988) suggests that the use of a diagnostic diagram to evaluate $K_W$ does not account for systematic distortion of the radial velocity curve. We therefore attempted to make use of the light centres method, as described by Marsh (1988). In the co-rotating co-ordinate system, the white dwarf has velocity $(0, -K_W)$, and symmetric emission, say from a disc, would be centred at that point. By plotting $K_x = -K \sin \phi_0$ versus $K_y = -K \cos \phi_0$ for the different radial velocity fits (Fig. 10), one finds that the points move closer to the $K_y$ axis with increasing Gaussian separation. A simple distortion which only affects low velocities, such as a bright spot, would result in this pattern, equivalent to a decrease in distortion as one measures emission closer to the velocity of the primary star. By extrapolating the last point on the light centre diagram to the $K_y$ axis, we measure the radial velocity semi-amplitude of the white dwarf $K_W = 93 \pm 10$ km s$^{-1}$. The error on $K_W$ was estimated from the uncertainty in crossing the $K_y$ axis, given the uncertainties associated with the points on the light centres diagram. Note the small scale on the $x$-axis of the light centres diagram.

4.7 Radial velocity of the secondary star

The secondary star in U Sco is observable through weak absorption lines, although many features have been drowned out by the nebular lines of the outburst. We compared regions of the spectra rich in absorption lines with several template dwarfs of spectral types F0–K2, the spectra of which are plotted in Fig. 10. The absorption features are too weak for the normal technique of cross-correlation to be successful in finding the value of $K_R$, but it is possible to exploit these features to obtain an estimate of $K_R$ using the technique of skew mapping. This technique is described by Smith, Cameron & Tucknott (1993).

The first step was to shift the spectral type template stars to correct for their radial velocities. We then normalized each spectrum by dividing by a spline fit to the continuum and then subtracting 1 to set the continuum to zero. This ensures that line strength is preserved along the spectrum. The U Sco spectra were also normalized in the same way. The template spectra were artificially broadened by 16 km s$^{-1}$ to account for orbital smearing of the U Sco spectra through the 1500 s exposures. The rotational velocity of the secondary star was found by the equation

$$q(1 + q)^2 = 9.6 \left(\frac{v \sin i}{K_R}\right)^3$$

(Smith & Dhillon 1998) using estimated values of $q$ and $K_R$ in the first instance, then iterating to find the best fit values given in Section 4.9. The templates were then broadened by this value of $v \sin i = 88$ km s$^{-1}$. Regions of the spectrum devoid of emission lines ($\lambda\lambda 5085 - 5395\AA$) were then cross-correlated with each of the templates yielding a time series of cross-correlation functions (CCFs) for each template star.

To produce the skew map (Fig. 10), these CCFs were back-projected in the same way as time-resolved spectra in standard Doppler tomography (Marsh & Horne 1988). If there is a detectable secondary star, we would expect a peak at $(0, K_R)$ in the skew map. This can be repeated for each of the templates.
Applying this $\gamma$ velocity to the skew map was seen to be displaced to the blue of the velocity curve fits in Section 4.6 is rest. The systemic velocity of U Sco derived from the radial velocity shifts the peak to the red, towards the $K_x = 0$ axis. As $K_x^2 < K_y^2$, then the value of $K_R$ is given by the equation

$$K_R = (K_x^2 + K_y^2)^{1/2} \approx K_y,$$

so $K_R$ changes little whilst varying $\gamma$.

The skew maps produced using each of the template stars with $\gamma = 0$ km s$^{-1}$ show well-defined peaks at $(K_x, K_y) \sim (-30, 160)$ km s$^{-1}$. However, applying $\gamma = 47$ km s$^{-1}$, the peaks in the skew maps shift to $(K_x, K_y) \sim (15, 180)$ km s$^{-1}$. We suspect that the true $\gamma$ value of U Sco falls between these two limits. The skew map shown in Fig. 11 is for the K2V spectral type template with $\gamma = 47$ km s$^{-1}$, and is arguably the best fitting template for the secondary star. The skew map shows a clear peak around $(K_x, K_y) \sim (10, 165)$ km s$^{-1}$. To bring the skew map peak to lie on $K_x = 0$, the $\gamma$ value must be modified to $\sim 30$ km s$^{-1}$, which still falls within 2$\sigma$ of the $\gamma$ derived from the emission lines. The resulting peak falls on $K_y = 170$ km s$^{-1}$, which we adopt as the radial velocity semi-amplitude for the secondary star: $K_R = 170 \pm 10$ km s$^{-1}$. The uncertainty in $K_R$ has been determined from the scatter in $K_R$ due to four sources of error: varying the $\gamma$ velocity; using different spectral type templates; producing skew maps from random subsets of the data; the accuracy in measuring the peak in the skew map.

The bottom panel of Fig. 11 shows a sine wave in the trailed CCFs, demonstrating that the peak in the skew map is not due to noise in the CCFs. It can be seen that the peaks in the CCFs are most prominent around primary eclipse ($\phi \sim 0.7–1.2$). There are two possible explanations for this. First, by considering the geometry of the secondary eclipse in U Sco, we estimate that a maximum of 30 per cent of the visible surface of U Sco will be obscured by the large accretion disc (see Section 4.9) between phases 0.35–0.65. We would therefore expect the peaks in the CCFs to weaken considerably at these phases, which is exactly as observed in Figure 11. This explanation is further supported by the tentative evidence for a secondary eclipse presented in the continuum light curve (Figure 4) and it does not affect the values for the masses we have derived in Section 4.9. Second, it is possible that the absorption features on the inner hemisphere of the secondary star are weakened by irradiation due to the recent outburst, which would again explain the loss of the peaks in the CCFs around phase 0.5. If the latter explanation were true, it is possible that we have overestimated the value of $K_R$, which would in turn lead us to overestimate $M_1$ (see Figure 14). The only way we can reliably account for any systematic effects due to irradiation would be to obtain higher signal-to-noise observations during quiescence and so measure $v \sin i$ during primary eclipse.

4.8 Rotational velocity and spectral type of the secondary star

Mass estimates of CVs using emission line studies suffer from systematic errors, and have been thoroughly discussed by a number of authors (e.g. Marsh 1988). More reliable mass estimates can be obtained by using $K_R$ in conjunction with the rotational velocity of the secondary star, $v \sin i$. We attempted to determine $v \sin i$ using the procedure outlined in Smith, Dhillon & Marsh (1998), but the data were too noisy.

Previous estimates of the secondary spectral type have ranged from F5V to K2III. Janes (1985) suggests G0±5III-V, corroborated by Webbink et al. (1987) with a GIII subgiant. Recent estimates have agreed on the subgiant nature

![Figure 9. Light centres diagram for HeII λ4686Å in U Sco.](image-url)
of the secondary. Schaefer (1990) estimated the spectral type as G3-6 from the colours at minimum light, whereas Johnston & Kulkarni (1992) measured the observed ratio of calcium lines to H$\delta$ and found F8$\pm$2. Based on the detection of the MgI$\delta$ absorption in the 1979 outburst spectrum, Kahabka et al. (1999) find the secondary to be consistent with a low-mass subgiant secondary of spectral type K2. This is supported by Anupama & Dewangan (2000), who estimate the secondary to be a K2 subgiant based on the indices of the MgI$\delta$ absorption band and the FeI + CaI absorption feature in the late-decline spectrum of the 1999 outburst. Unfortunately, as can be seen in Fig. 10, it is impossible to confirm a secondary spectral type using our data, although the MgI$\delta$ complex is clearly present.

4.9 System Parameters

The radial velocity curves show little or no phase shift, giving us confidence that our measurement of $K_W$ reflects the motion of the white dwarf. Hence, together with $K_R$, our newly derived period and a measurement of the eclipse full width at half-depth ($\Delta\phi_{1/2}$), we can proceed to calculate accurate masses free of many of the assumptions which commonly plague CV mass determinations. Our white dwarf radial velocity semi-amplitude, $K_W = 93 \pm 10$ km s$^{-1}$ compares favourably with the previous measurement of $K_W = 95 \pm 50$ km s$^{-1}$ by Barlow et al. (1981) after the 1979 outburst. Schaefer & Ringwald (1995) derived the values $K_W = 87 \pm 32$ km s$^{-1}$ and $K_R = 56 \pm 27$ km s$^{-1}$, but concluded that these results were unreliable due to inconsistent $\gamma$ velocities, a phase shift in the emission lines and a large scatter in the radial velocity curves.

In order to determine $\Delta\phi_{1/2}$, we estimated the levels of flux outside the eclipse (the principle source of the error) and at eclipse minimum, and then measured the full width of eclipse half way between these points. The eclipse full width at half-depth for U Sco was measured to be $\Delta\phi_{1/2} = 0.104 \pm 0.01$, in good agreement with $\Delta\phi_{1/2} = 0.106 \pm 0.01$ cited by Schaefer & Ringwald (1995).

We have opted for a Monte Carlo approach similar to that of Horne, Welsh & Wade (1993) to calculate the system parameters and their errors. For a given set of $K_W$, $K_R$, $\gamma$...
Figure 12. Constraints on the masses of the stars in U Sco. Each dot represents an \((M_1, M_2)\) pair. The dashed lines are lines of constant inclination \((i = 80^\circ, i = 85^\circ, i = 90^\circ)\). The solid curves satisfy the constraints on \(K_W = 93 \pm 10\, \text{km} \, s^{-1}\) and \(K_R = 170 \pm 10\, \text{km} \, s^{-1}\).

\[ \Delta \phi_{1/2} \text{ and } P, \text{ other system parameters are calculated as follows.} \]

The mass ratio, \(q\), can be determined from the ratio of the radial velocities

\[ q = \frac{M_1}{M_2} = \frac{K_W}{K_R}. \tag{4} \]

\(R_2/a\) can be estimated because we know that the secondary star fills its Roche lobe (as there is an accretion disc present and hence mass transfer). \(R_2\) is the equatorial radius of the secondary star and \(a\) is the binary separation. We used Eggleton’s formula \citep{Eggleton1983} which gives the volume-equivalent radius of the Roche lobe to better than 1 per cent, which is close to the equatorial radius of the secondary star as seen during eclipse,

\[ \frac{R_2}{a} = \frac{0.49q^{2/3}}{0.6q^{2/3} + \ln(1 + q^{1/3})}. \tag{5} \]

By considering the geometry of a point eclipse by a spherical body \citep[e.g.][]{Dhillon1991}, the radius of the secondary can be shown to be

\[ \left( \frac{R_2}{a} \right)^2 = \sin^2\pi \Delta \phi_{1/2} + \cos^2 \pi \Delta \phi_{1/2} \cos^2 i. \tag{6} \]

Using the value of \(R_2/a\) obtained from equation (5), combined with equation (4), the inclination of the system can be found. Kepler’s Third Law gives

\[ \frac{K_W^3 P_{orb}}{2\pi G} = \frac{M_1 \sin^3 i}{(1 + q)^2} \tag{7} \]

which, with the values of \(q\) and \(i\) calculated using equations (4) and (5), gives the mass of the primary star. The mass of the secondary star can then be obtained using equation (4).

The distance of each component to the centre of mass of the system \((a_1, a_2)\), is given by

\[ a_{(1,2)} = \frac{K(W,R)P}{2\pi \sin i}. \tag{8} \]

The separation of the two components, \(a\), is \(a_1 + a_2\), allowing the radius of the secondary star, \(R_2\), to be calculated from equation (6).

The Monte Carlo simulation takes 10 000 values of \(K_W\), \(K_R\), and \(\Delta \phi_{1/2}\) (the error on the period is deemed to be negligible in comparison to the errors on \(K_W\), \(K_R\), and \(\Delta \phi_{1/2}\)), treating each as being normally distributed about their measured values with standard deviations equal to the errors on the measurements. We then calculate the masses of the components, the inclination of the system, the radius of the secondary star, and the separation of the components, as outlined above, omitting \((K_W, K_R, \Delta \phi_{1/2})\) triplets which are inconsistent with \(\sin i \leq 1\). Each accepted \(M_1, M_2\)
The recurrent nova U Sco

Table 4. System parameters for U Sco

| Parameter | Measured Value | Monte Carlo Value |
|-----------|----------------|-------------------|
| \(P_{\text{orb}}\) (d) | 1.2305522 | | |
| \(K_W\) (km s\(^{-1}\)) | 93 ± 10 | 95 ± 9 | |
| \(K_R\) (km s\(^{-1}\)) | 170 ± 10 | 169 ± 10 | |
| \(\Delta \phi_{1/2}\) | 0.104 ± 0.010 | 0.098 ± 0.007 | |
| \(q\) | 0.55 ± 0.07 | | |
| \(i^\circ\) | 82.7 ± 2.9 | | |
| \(M_1/M_2\) | 1.55 ± 0.24 | | |
| \(M_2/M_\odot\) | 0.88 ± 0.17 | | |
| \(R_2/R_\odot\) | 2.1 ± 0.2 | | |
| \(a/R_\odot\) | 6.5 ± 0.4 | | |
| \(\Delta \phi\) | 0.12 ± 0.01 | | |
| \(R_D/R_1\) | 0.87 ± 0.11 | | |

5 DISCUSSION

5.1 TNR Model

The outburst events in RNe could be the result of the TNR model, as seen in classical novae, or the disc instability model of dwarf novae. It is likely that given the heterogeneous nature of RNe, the mechanism depends on the individual system (Webbink 1990). In the case of U Sco, the TNR model was suggested in the light of severe problems with the disc instability model (Webbink et al. 1987). The motivation behind measuring the mass of the white dwarf in U Sco was to give positive confirmation that outbursts are the result of a TNR, which predicts that the higher the mass of the white dwarf, the more frequent the outbursts. For eruptions to recur on the timescale of the deep eclipse seen in U Sco (\(\sim 8\) years), the mass of the white dwarf must be very close to the Chandrasekhar mass of 1.378\(M_\odot\) (Starrfield, Sparks & Truran 1982, Starrfield, Sparks & Shaviv 1985, Nomoto, Thielemann & Yokoi 1984). Our observations allow us to calculate the mass of the white dwarf in U Sco to be \(M_1 = 1.55\pm0.24M_\odot\). Despite the large error on the value, we can conclude that U Sco contains a high mass white dwarf, although additional work, such as an accurate \(v \sin i\) determination during quiescence, must be done to further constrain this.

5.2 U Sco as a Type Ia SN Progenitor

Type Ia supernovae (SNe Ia) are widely believed to be thermonuclear explosions of mass-accreting white dwarfs (see Nomoto, Iwamoto & Kishimoto 1997 for a review). The favoured model for progenitor binary systems is the Chandrasekhar mass model, in which a mass-accreting carbon-oxygen white dwarf grows in mass up to the Chandrasekhar limit and then explodes as a SN Ia. For the evolution of accreting WDs towards the Chandrasekhar mass, two scenarios have been proposed. The first is a double degenerate scenario, where two white dwarfs merge to cross the Chandrasekhar limit. A candidate for this has been identified in KPD 1930+2752 (Maxted, Marsh & North 2000). The second is a single degenerate scenario, where matter is accreted via mass transfer from a stellar companion. A new evolutionary path for single degenerate progenitor systems is discussed by Hachisu et al. (1999), which describes how the secondary (a slightly evolved main-sequence star) becomes helium rich. Their progenitor model predicts helium enriched matter accretion onto a white dwarf. Objects which display these characteristics in the form of strong HeII \(\lambda 4686\ang\) lines are luminous super-soft X-ray sources and certain recurrent novae, such as U Sco and the others in the U Sco subclass (V394 CrA and LMC-RN). The observations in this paper, in confirming the helium rich accreted matter, and constraining the white dwarf mass to be near the Chandrasekhar mass, make U Sco the best candidate for this evolutionary path to a SN Ia.

The time to supernova can be estimated by dividing the amount of mass required to reach the Chandrasekhar mass by the average mass accretion rate (\(\dot{M}_{\text{ave}}\)). Our results suggest a minimum white dwarf mass of \(\sim 1.31M_\odot\), which requires it to accrete approximately 0.07\(M_\odot\) to become a SN Ia. In their model, Hachisu et al. (2000b) find that the white dwarf in U Sco grows in mass at an average rate of \(\dot{M}_{\text{ave}} \sim 1.0 \times 10^{-7}M_\odot\ yr^{-1}\). Using this value, we therefore predict U Sco to become a supernova within \(\sim 700,000\) years.

6 CONCLUSIONS

(i) We have shown that U Sco contains a high mass white
dwarf ($M_1 = 1.55 \pm 0.24 M_\odot$), confirming that the outburst mechanism is the TNR model.

(ii) The presence of an accretion disc has been confirmed for the first time by clear evidence of rotational disturbance in the HeII emission lines during eclipse, as well as their double-peaked nature.

(iii) The secondary star has a radius of $2.1 \pm 0.2 R_\odot$, consistent with the idea that it is evolved.

(iv) The mass of the white dwarf in U Sco is $M_1 = 1.55 \pm 0.24 M_\odot$, implying that it is the best SN Ia candidate known and is expected to explode in $\sim 700000$ years.

ACKNOWLEDGEMENTS
We would like to thank Katsura Matsumoto, Taichi Kato and Izumi Hachisu for their light curve of U Sco during the 1999 outburst, and Chris Watson for useful comments. TDT and SPL are supported by PPARC studentships. The authors acknowledge the data analysis facilities at Sheffield provided by the Starlink Project which is run by CCLRC on behalf of PPARC. The Anglo-Australian Telescope is operated at Siding Springs by the AAO.
