Abstract

Background: Antibody fragments selected from large combinatorial libraries have numerous applications in diagnosis and therapy. Most existing antibody repertoires are derived from human immunoglobulin genes. Genes from other species can, however, also be used. Because of the way in which gene conversion introduces diversity, the naïve antibody repertoire of the chicken can easily be accessed using only two sets of primers.

Results: With in vitro diagnostic applications in mind, we have constructed a large library of recombinant filamentous bacteriophages displaying single chain antibody fragments derived from combinatorial pairings of chicken variable heavy and light chains. Synthetically randomised complementarity determining regions are included in some of the heavy chains. Single chain antibody fragments that recognise haptens, proteins and virus particles were selected from this repertoire. Affinities of three different antibody fragments were determined using surface plasmon resonance. Two were in the low nanomolar and one in the subnanomolar range. To illustrate the practical value of antibodies from the library, phage displayed single chain fragments were incorporated into ELISAs aimed at detecting African horsesickness and bluetongue virus particles. Virus antibodies were detected in a competitive ELISA.

Conclusion: The chicken-derived phage library described here is expected to be a versatile source of recombinant antibody fragments directed against a wide variety of antigens. It has the potential to provide monoclonal reagents with applications in research and diagnostics. For in vitro applications, naïve phage libraries based on avian donors may prove to be useful adjuncts to the selectable antibody repertoires that already exist.

Background

Recombinant antibodies derived from phage display libraries [1-10] are by now well established in medicine and biotechnology. A major objective of recombinant antibody research so far has been to develop new therapeutic agents for use in human patients. Accordingly,
most of the existing large combinatorial libraries are based upon human immunoglobulin genes. Phage antibodies can, however, be derived from a number of alternative donors such as rabbits [11], camels [12], cattle [13], sheep [14] and chickens [15]. From a practical point of view, the chicken is a particularly attractive source of immunoglobulin genes. To amplify each of the V gene segments in the human or mouse requires a number of PCR primer sets. In contrast, the chicken antibody repertoire can be accessed relatively easily because of the way in which its diversity is generated. In birds, single immunoglobulin variable and joining gene segments at each heavy (H) and light (L) chain locus are subjected to V(D)J rearrangement in the case of the L chain and VDJ for the H chain. Variability then arises by gene conversion resulting from the incorporation of pseudo V region genes [16-19]. As a result, essentially all chicken V regions can be expected to have virtually identical amino acid sequences at both termini. The naïve antibody repertoire can thus be conveniently amplified by using only a single set of PCR primers for the H chain and another for the L chain. This property was first exploited by Davies and co-workers [15] who constructed and expressed an scFv library derived from chicken bursal lymphocyte RNA. They demonstrated the potential of the chicken as a source of recombinant antibody fragments by constructing a relatively small (2.7 × 10⁷ clones), but nonetheless effective, naïve library by constructing a relatively small (2.7 × 10⁷ clones), but nonetheless effective, naïve library by constructing a relatively small (2.7 × 10⁷ clones), but nonetheless effective, naïve library by constructing a relatively small (2.7 × 10⁷ clones), but nonetheless effective, naïve library by constructing a relatively small (2.7 × 10⁷ clones), but nonetheless effective, naïve library by constructing a relatively small (2.7 × 10⁷ clones), but nonetheless effective, naïve library. Antibody fragments that recognise proteins are not always readily obtained from small libraries of human origin [3].

The accessibility by PCR of chicken antibody gene repertoires also facilitates the construction of immune phage libraries [20-22]. If, however, the aim is to bypass immunisation entirely, it becomes important to increase the probability of isolating high affinity binders by having as large and diverse a repertoire as possible [5-7,23,24]. While the construction of a large antibody library is not a trivial undertaking, the technology ultimately offers several advantages when compared to conventional sources of antibodies, particularly the way in which the need for animals or cell culture facilities is circumvented. To be able to understand and control new or re-emerging diseases, new reagents are constantly required for use in veterinary and agricultural diagnostic tests and as research tools. A rapid and economical way of obtaining pathogen-specific antibodies is therefore likely to be especially useful in developing countries where budgets and facilities are often severely limited. Because of the potential of recombinant antibody technology to provide reagents that can be used in a variety of standard immunodiagnostic tests [4,25-29] we have constructed a large (approximately 2 × 10⁹ clones) and diverse scFv library, primarily with in vitro diagnostics in mind. This library combines the naïve chicken immunoglobulin repertoire with a sub-library in which amino acid residues comprising the third H chain complementarity determining region (CDR3) have been synthetically randomised. The overall repertoire was found to be diverse enough to yield antibody fragments that recognise haptens, proteins and viruses. Its potential as a source of in vitro veterinary diagnostic reagents was illustrated by finding antibodies which could be used in ELISA to detect African horse sickness virus (AHSV), bluetongue virus (BTV) and BTV antibodies.

Results

Antibody fragment library construction

With the goal of creating a widely diverse antibody repertoire, two separate phage display sublibraries were constructed. The first was aimed at representing the naïve immunoglobulin repertoire of the chicken. For this, pooled RNA extracted from five chicken bursae was used. A strategy was employed in which the 5’ PCR primer used to amplify the L chain and the 3’ of the H chain included complementary sequences, which when extended, would serve to link the H and L chains via a (Gly₄ Ser)₃ linker [30]. This naïve sublibrary comprised a total of 3.75 × 10⁸ phage clones. DNA from a number of these clones was sequenced to verify that joining had taken place correctly and that reading frames had been preserved. This analysis also revealed that the CDR3 of the H chain of the sequenced clones varied in size from 6 to 19 residues (Figure 1A). Attempts to use this same joining strategy to introduce artificially randomised CDR3s of defined size were not consistently successful. Accordingly, a separate linker sequence was amplified from a DNA template obtained from a clone in the naïve library and splicing by overlap extension (SOE) PCR [31] was used to join separate H, L and linker sequences [32]. The H chains included artificially randomised CDR3s ranging in size from 6 to 14 amino acid residues. A separate set of amplification and joining reactions was carried out for each size of CDR. After joining, the H and L chain sets were ligated into the display vector pHEN I and each set was separately electroporated into competent bacterial cells. DNA sequencing showed that randomised CDR3 sequences of defined lengths had been successfully incorporated into the heavy chains (Figure 1B). Based on the number of primary transformants, phages were mixed proportionally to prevent over-representation of any of the synthetic CDR3s in the synthetic sublibrary. The naïve and randomised sublibraries were similarly combined to yield the final repertoire consisting of approximately 2 × 10⁹ primary transformants. This required a total of 190 separate electroporations. Sequencing the DNA of 70 random clones revealed that approximately 65% had the potential to express in-frame scFvs. The completed library thus contained combinatorial pairings of naïve H and L chains as well as sets of
synthetically randomised H chains paired with natural chicken L chains.

**Selection of specific antibodies**

To test its viability as a source of antibody fragments, the entire library was subjected to four rounds of selection using several model haptens, proteins and viruses. Rescued phage particles obtained after each round of panning were then tested in a polyclonal phage ELISA to determine whether enrichment for binders had taken place with each successive selection step. An increase in specific ELISA signals was evident with the phage pools obtained after...
Polyclonal phage ELISA. Polyclonal phage ELISAs showing the increase in specific signal with successive rounds of panning. Phages were selected by panning on immobilised proteins, hapten and viruses. Pools released from the affinity matrix after each round of selection were amplified, purified by precipitation and tested for binding to the homologous target and several heterologous antigens: BSA = bovine serum albumin, MP = 2% milk powder in PBS, MBP = maltose binding protein, F-BSA = fluorescein-conjugated bovine serum albumin, N-BSA = 4-hydroxy-3-ido-5-nitrophenylacetic acid conjugated to bovine serum albumin, AHSV = purified African horsesickness virus particles, BTV = purified bluetongue virus particles, CMV = purified cucumber mosaic virus particles, CYT = cytochrome C, THY = porcine thyroglobulin, CHY = chymotrypsinogen, KLH = keyhole limpet haemocyanin, TEL = turkey egg lysozyme. The homologous antigens in each case were: A) F-BSA, B) N-BSA, C) KLH, D) TEL, E) CYT, F) THY, G) CMV, H) AHSV and I) BTV. Figures on the X axis indicate the panning round of which the output was tested for polyclonal binding. The figure 0 refers to the unpanned library.
Figure 3
Amino acid sequences of CDRs of binding antibodies. Amino acid sequences of VH and VL CDRs of antibodies selected from the Nkuku library. Asterisks (*) denote clones which have high probability of having been derived from the portion of the library into which synthetic CDR3s were introduced. The entire H chain of clone C31 was absent, but the fragment bound to CMV particles in ELISA (not shown). The antigens recognised by each of the individual clones are indicated in the figure. Dots (.) indicate spaces introduced to align sequences, x denotes ambiguous bases. Antigen-specific phage pools selected on some of the viruses and proteins were chosen for further characterisation. Individual phage clones were picked and tested in ELISA for their ability to bind, supernatant. After affinity purification, yields of soluble fragments were not normalised for each ELISA determination, as a rule, no reactivity with unrelated antigens was discernible indicating that improved binding to the target with each round of panning was due to specific enrichment and not an increase in “stickiness” and/or phage titre. One exception was that the polyclonal phage displayed antibodies selected on TEL showed an unexpected cross-reactivity with porcine thyroglobulin (Figure 2D). Selecting single clones, however, made it possible to isolate a phage displayed antibody that recognised only TEL and another that recognised both TEL and thyroglobulin (not shown).

In an attempt to establish whether any of the binding antibodies were derived from the component of the library that included the synthetically randomised VH CDR3s, DNA coding for several virus-specific binders was sequenced, namely three each that recognised BTV and AHSS and five that bound to CMV. Based on the nucleotide sequences used to introduce the synthetic CDR as well as the presence of only NNK codons in the CDR3 itself, one clone from each of these groups could be shown to have originated from the synthetic component of the final library (Figure 3). No two L or H chains were identical and (surprisingly) one clone (C31) that bound to CMV lacked its entire VH region which indicates that its total binding activity resides in the VL region. A number of phage antibody clones specific for BTV and CMV were tested for their ability to bind as soluble scFvs. Soluble fragment production was induced using IPTG. Of fourteen BTV binders, only two showed ELISA reactivity in both forms. With CMV, the figure was 85 out of 96, but since their DNA sequences were not determined, this figure may reflect multiple copies of fewer actual binders. For BIACORE affinity determinations, the scFvs were directly tested for their ability to bind in soluble form. After affinity purification, yields of soluble fragments ranged from 4 ng to 2,5 µg per millilitre of culture supernatant.
Sandwich ELISA to detect orbiviruses

African horsesickness is an economically important disease in southern Africa and elsewhere. It is caused by AHSV, an orbivirus (family Reoviridae) containing a characteristic double-stranded RNA segmented genome within a double-shelled capsid. AHSV can be detected by using a sandwich ELISA in which the virus particle is first captured on an affinity matrix of immobilised antibodies and then detected by a second layer of virus-specific antibodies followed by labelled anti-immunoglobulin reagents [33,34]. Phage antibodies are particularly suitable in this format since the detecting signal is amplified by the multiple copies of pVIII, the major capsid protein of the fusion phage. To determine whether the chicken antibody library could provide phage antibodies that could act as the second antibody in the sandwich, round three output phages (Figure 2H) were screened by panning on 2.5 μg/ml of AHSV instead of the usual concentration of 20 μg/ml. This was done in an attempt to exclude low or medium affinity binders by using a limiting amount of target antigen. Only three virus-specific scFvs were found after this high-stringency round of selection. The clone that gave the highest signal (Figure 3; clone Lca12) was chosen for use as a detecting antibody in the sandwich ELISA. For this assay, virus particles were trapped from suspension using virus-specific rabbit IgG and detected using the phage displayed scFv, an anti-pVIII mouse monoclonal antibody (mAb) and a labelled anti-mouse IgG immunoglobulin. Each point represents the average of three determinations. Error bars show one standard deviation from the mean.

Figure 4

**Sandwich ELISA for virus detection.** Double antibody sandwich ELISA absorbance values obtained in which dilutions of (A) AHSV or (B) BTV particles were trapped from suspension using virus-specific rabbit IgG and detected using phage-displayed scFvs (clone Lca12 for AHSV, clone H2 for BTV; see Figure 3) as the second antibody in the sandwich. Binding phages were detected with a pVIII-specific mAb and a peroxidase-labelled anti-mouse IgG immunoglobulin. Each point represents the average of three determinations. Error bars show one standard deviation from the mean.

**Inhibition ELISA**

The specificity of an antigen-antibody interaction can be shown by inhibiting the binding with a different antibody directed against the same antigen. Such inhibition assays are used to detect antibodies against BTV for the purposes...
of regulating livestock exports. To determine whether BTV-specific scFvs could replace the traditional mAbs usually used in these tests, BTV particles were immobilised by adsorption to a microtitre plate well and immune- and control sera from rabbits or sheep were added before introducing a BTV-specific scFv (Figure 3; clone H2). The binding of the antibody fragment was inhibited by virus-specific antibodies in the sera, the degree of inhibition being dependent on the serum dilution. Rabbit antiserum directed against both the homologous serotype 10 as well as the heterologous serotype 4 showed inhibition. Similarly, sheep antisera raised against three heterologous serotypes (2, 4 and 9) could inhibit the interaction. Non-immune sera from either species had no effect on the ELISA signal and filamentous phage displaying no scFvs did not bind to the immobilised BTV serotype 10 is shown by (q).

**Affinity of selected scFvs**

To determine whether binding affinities of Nkuku-derived scFvs had the potential to be in the same range as those obtained from other large libraries, scFvs directed against three antigens of widely different molecular weights were chosen for BIACORE analysis. These were fluorescein (586 Da), cytochrome C (12.4 kDa) and KLH (400 kDa). All determinations were done in duplicate using separate preparations of scFvs. The experimental results were fitted to the BIACore evaluation 1:1 Langmuir binding model. Visual comparison and the calculated $\chi^2$ values indicated an
acceptable fit to the model. The high affinities of these three binders (nanomolar or less; Table 2) show that they compare well with antibody fragments derived from naïve libraries of human origin [5,7].

Discussion
Most recombinant antibody libraries are based on human immunoglobulin genes. While this is obviously desirable in human therapy, for veterinary diagnostic tests or other in vitro applications, specific binding reagents could be obtained from any animal source. With veterinary and agricultural applications in mind, we were able to construct a diverse phagemid-based chicken scFv library consisting of approximately two billion clones. Several other large antibody libraries have been given a variety of names (e.g. “Nissim”, “Vaughan”, “HuCal”, “n-CoDer” etc). Accordingly, we suggest for our library the name “Nkuku”, derived from the Zulu word “nkukhu”, which means “chicken”.

To maximise the range of potential paratopes [3], the Nkuku library makes use of the natural L and H chains of the chicken immunoglobulin repertoire together with a selection of synthetically randomised H chain CDR3s of defined sizes. The success of this diversification strategy was shown empirically by obtaining scFvs that recognised a number of haptons, proteins and viruses. Isolating a variety of target-specific phage antibodies further demonstrates the suitability of the chicken as a donor of immunoglobulin genes for use in constructing non-immune antibody libraries [15]. Two different approaches to the combinatorial joining of H and L chains were used. The use of amplification primers that included the linker sequences [21] was not feasible for incorporating randomised H chain CDR3s owing to the impractically long oligonucleotides required (not shown). For constructing the synthetically randomised sublibrary, the classical strategy of employing a separate linker sequence [32] was therefore used. For similar reasons, it was also not possible to reliably include synthetic CDR3s of longer than 14 residues. The final antibody pool therefore relies on the chicken’s natural H chain repertoire to provide these longer CDRs. Producing the antibody library was nevertheless straightforward, since all amplification steps were facilitated by the relatively few PCR primers required.

The amino acids comprising the CDR3 of the human immunoglobulin H chain show the most variability and usually make the dominant contribution to binding [35-37]. In the widely distributed human antibody library made by Nissim and co-workers [4], it is this region that has been artificially randomised. Sequencing the DNA of several unselected clones from our chicken library revealed VH CDR3 regions ranging in size from 6 to 19

---

1Association and dissociation rate constants were measured using BIACORE. Each value represents the average of two independent determinations on the same chip surface.
residues. The CDR3 regions of the L chain were from 5 to 13 amino acids long, also showing wide variability. Since chicken IgY has essentially the same arrangement of CDRs as mammalian IgG, we emulated the Nissim library approach by incorporating our synthetically randomised sequences into the VH CDR3 region [4]. To verify that the randomised VH CDR3 sequences were used in our functional antibodies, the DNA coding for 11 antibody clones that had been selected by panning on three different immobilised viruses was sequenced. It was expected that in the clones originating from the artificially introduced CDR3 sequences, all residues flanking the CDR would be identical to those of the primers used to introduce them. In addition, since NNK codons were used for randomisation, every third base in the synthetic CDR should be either G or T. On the basis of these criteria, three out of the 11 clones appeared to originate from the synthetically introduced repertoire. All L chains were found to be different. In the case of both BTV and AHSV, one out of three binding clones probably originated from the synthetic repertoire while with CMV the proportion was one in five. We also found that one of the antibodies that bound to CMV was lacking its entire H chain (Figure 3; clone C31). Its binding in ELISA was nonetheless essentially indistinguishable from that of several other intact phage displayed scFvFs (not shown). It is unlikely that the absent H chain represents a sequencing artefact since the entire insert was sequenced in both directions using primers that anneal to the vector. Extensive gene conversion in chicken L chains has been observed before [21] and raises the intriguing possibility that it may be possible to develop a functional single domain antibody library from only the chicken L chain.

Not all chicken library antibodies that bound as phage displayed fragments could be shown to bind in ELISA when expressed as scFvFs. This is not unexpected and could be due either to low expression levels or to a low intrinsic affinity when the fragment is used outside the phage display context. The phage particle with its displayed antibody fragment can nevertheless be a useful ELISA reagent when used as the second antibody in a sandwich format. This was shown in the immunoassay (Figure 4A) designed to detect AHSV particles immobilised on a rabbit IgG affinity matrix using clone Lca12 (Figure 3). An analogous assay for the structurally similar BTV, but using fusion phages from a human antibody library [4], has been described previously [25]. The ability of Nkuku library-derived fusion phages to be incorporated into an assay for viral antibodies as opposed to antigens was shown by the BTV-specific fusion phage designated H2 which could be inhibited by immune rabbit and sheep sera (Figure 5). Inhibition was not confined to antibodies directed against the homologous serotype, indicating that H2 probably recognises an antigenic determinant that occurs on more than one viral serotype. Alternatively, it may bind to a unique region that is located in close proximity to one or more cross-reactive epitopes, such that it is functionally inhibited by heterologous antibodies. Our results show that the Nkuku library can be used to obtain potentially useful and specific assay reagents without resorting to hybridomas. In the case of viruses possessing a multiplicity of serotypes such as the orbiviruses AHSV and BTV [38], recombinant technology may be the only practical way of obtaining antibodies that can identify each individual serotype.

A DNA clone that codes for a particular recombinant antibody is a virtually inexhaustible source which can be unequivocally identified by its nucleotide sequence. Critical immunoassay reagents can therefore be fully characterised. In addition, it is often possible to engineer or evolve phage antibodies showing improved stability or affinity [39]. Most of the antibodies described here bound strongly in ELISA without further modification and at least one (F10) could survive at least one freeze-thaw cycle. This may not always be the case and if the aim is to develop immunoassays for use under field conditions e.g. in Africa, it may be necessary to select for temperature-stable variants. The use of chicken frameworks may be advantageous for this purpose since they have evolved to function at a body temperature approximately 5°C higher than that of humans.

Conclusions
On the basis of the evaluation described here, this chicken-derived "Nkuku" phage library is a potentially versatile source of recombinant antibody fragments which should find many applications in areas such as immunodiagnostics [40] and proteomics [41]. Unless steps are taken to humanise them [21], such avian antibodies are unlikely to be useful for human therapeutics. Human V genes may, however, sometimes lack the intrinsic features required to produce antibodies that can recognise all epitopes with high affinity [42]. For in vitro use, large non-immune phage libraries based on avian donors such as the one described here may therefore prove to be a useful additional source of binding reagents.

Methods
Antigens and immunochemical reagents
Attenuated AHSV serotype 3 and BTV serotype 10 (both members of the genus *Orbivirus*, family *Reoviridae*) were obtained originally from the vaccine factory (now Onderstepoort Biological Products Limited) at the then Veterinary Research Institute. The viruses were multiplied in BHK (BTV) or CER (AHSV) cells and purified by sucrose density-gradient centrifugation [43]. Rabbit and sheep sera were supplied by the Biochemistry and Virology Divisions of the Onderstepoort Veterinary Institute. The sheep
sera are used routinely as reference standards by the OIE World Reference Centre for bluetongue virus. Purified cucumber mosaic virus particles were a generous gift from Dr G. Pietersen, Plant Protection Research Institute, Roodplaat. KLF, F-BSA, porcine thyroglobulin, TEL and cytochrome C were from Sigma. N-BSA was prepared from the succinimide ester of 4-hydroxy-3-iodo-5-nitrophenylacetonic acid -CAP-OH (NIP-CAP-OSU; Genosys) and BSA fraction V according to the method described by the Medical Research Council (Cambridge, UK) in the instructions issued with their "Nissim" antibody library. B62-FE2, a mAb specific for an epitope on the phage coat protein VIII of filamentous male-specific phages, was from Progen Biotechnik (Heidelberg) while a horseradish peroxidase (HRP)-labelled anti-M13 mAb was purchased from Amersham Pharmacia Biotech (UK). HRP labelled rabbit-anti-mouse immunoglobulins were supplied by Dako (Denmark). A murine hybridoma (Mycl-9E10; ECACC 85102202) producing a mAb (9E10) specific for the c-myc epitope tag, was used to obtain the rabbit antibody fraction by overnight cutting with pentobarbitone and their bursae were removed (approved by the Animal Ethics Committee, Ondersteypoort Veterinary Institute). Total RNA was extracted with TRI-Reagent (Molecular Research Center, Cincinnati, OH, USA). Oligo d(T)16 primer, RNase inhib-itor, MuLV reverse transcriptase (all from the Perkin Elmer Gene Amp RNA PCR core kit, Roche), 10x Ex Taq buffer and dNTPs (both from TaKaRa, Japan) were used for cDNA synthesis. The reaction products were used directly as cDNA templates to construct two different scFv gene sublibraries; the first was a naïve library while the second included a synthetically randomised H-chain CDR3 region. In both sublibraries the VH and VL genes were included a synthetically randomised H-chain CDR3 region. In both sublibraries the VH and VL genes were amplified using primer sets Sfi1L/NEWLVarH and NEWLVarL/LCNOT1 (Table 1). Amplification reactions consisted of 8 µl TaKaRa buffer, 2.5 pmol of each primer, 2.5 units (U) of TaKaRa Ex Taq enzyme, the 20 µl reverse transcription product (above) and water to a final volume of 100 µl. PCR was for 30 cycles at 94°C for 1 minute (min), 60°C for 1 min, 72°C for 1 min followed by a final extension period of 1 min at 72°C. The primers NEWLVarH and NEWLVarL contained overlapping linker sequences to allow the two genes to be spliced by overlap extension [21,31]. Prior to splicing, the amplified genes were purified using a QIAquick PCR purification kit (QIAGEN, Germany).

Further purification entailed electrophoresis on a 2% agarose gel (Seakem ME) prepared in 1 x TAE supplemented with a final concentration of 10 µg/ml crystal violet [44] followed by extraction from the gel using a QIAquick gel extraction kit (QIAGEN). Splicing was in 100 µl reaction volumes comprising 10 µl 10x TaKaRa buffer, 8 µl TaKaRa dNTPs, 100 ng VL chain DNA, 100 ng VH chain DNA, 2.5 U TaKaRa Ex Taq DNA polymerase, 3 U Promega Pfu DNA polymerase [45] and water to a final volume of 100 µl. The reaction components were transferred from ice to a preheated (94°C) thermal cycler. This was followed by 15 cycles at 94°C for 1 min, 60°C for 1 min, 72°C for 2 min and a final extension at 72°C for 5 min. Pullthrough amplification reactions consisted of 10 µl 10x TaKaRa PCR buffer, 8 µl TaKaRa dNTPs, 20 pmol Sfi1 primer, 2 µl spliced product, 2.5 U Ex Taq DNA polymerase and water to a final volume of 100 µl. Reaction mixtures were transferred from ice to a thermal cycler block at 94°C. A preheating step of 1 min at 94°C was followed by 25 cycles of 94°C for 1 min, 60°C for 1 min, 72°C for 2 min and a final extension at 72°C for 5 min. The product was gel purified as above. The joined VH and VL genes were digested overnight at 50°C with 20 U Sfi1 (Roche) per µg DNA in 100 µl buffer M (Roche) supplemented with 0.1 mg/ml acetylated BSA. For over-night cutting with NotI at 37°C, digestion conditions were adjusted by the addition of 1.5 µl of 5 M NaCl, 6 µl 1 M Tris (pH 8.0), 0.5 µl 10 mg/ml acetylated BSA, 20 U NotI (Roche) per µg DNA and water to final volume of 150 µl. The digested DNA was gel purified as above.

The phagemid vector pHEN I (obtained from the Medical Research Council, UK) was purified from an overnight TG1 bacterial culture using a QIAGEN Plasmid Midi Kit. Restriction enzyme digestion conditions were as described for the insert, but with six units of enzyme per µg of vector DNA. The digested vector was purified in the same way as the insert, but using a 1% agarose gel. Ligation reactions were incubated overnight at 16°C using 100 ng cut vector, 40 ng insert, 1 µl 10x ligation buffer (Roche), 0.5 U T4 DNA ligase and water to a final volume of 10.5 µl. The ligated product was first purified using a QIAquick PCR purification kit followed by a diffusion desalting step [46].

The desalted DNA was electroporated into Epicurian Coli Electroporation-Competent TG1 cells (Stratagene, USA) using a Biorad Gene Pulser II electroporator set on 1700 V, 200 Ω and 25 µF with 0.1 cm electroporation cuvettes. After electroporation the bacterial cells were immediately transferred to 1 ml SOC medium. After 1 hour (h) at 37°C in a shaking incubator they were plated onto 243 x 243 mm TYE agar plates (15 g agar, 8 g NaCl, 1 g tryptone, 5 g yeast in 1 l double distilled deionised water) supplemented with 100 µg/ml ampicillin and 2% glucose. Addi-
tional serial dilutions were plated to determine the library size. After an overnight incubation at 30°C the bacteria were scraped off the plates in 2x TY (16 g tryptone, 10 g yeast extract, 5 g NaCl dissolved in 1 l double distilled deionised water) supplemented with 100 µg/ml ampicillin and 2% glucose (2x TY A/G). The bacterial suspensions were stored as 15% glycerol stocks at -70°C. Ligations and electroporations were repeated until the required number of primary clones was obtained.

For the sublibrary containing synthetically randomised VH CDR3 areas, the VH gene, the linker sequence and the VL genes were amplified separately prior to joining all three components by overlap extension [32]. The VH gene was prepared as described for the naïve library. Nine different subrepertoires were constructed, each with a different synthetically randomised VH CDR3 region ranging in size from six to 14 amino acid residues. The primer on the 5’ end of VH gene (SfiI) was the same for all nine subrepertoires, whereas nine different primers were used on the 3’ end (Rα6VH, Rand7VH etc.; see Table 1). Amplification of the joined genes after SOE [31] was performed by using primer set SfiI/LCNOT1. The linker fragment was amplified with primer set GSfor/GSrev2 using a DNA template obtained from a sequenced clone in the naïve library. All the methods and conditions as used for the naïve sublibrary were implemented except for the SOE reactions where 40 ng VL DNA, 40 ng VH DNA and 54 ng linker per reaction were joined.

Phages were rescued from a pool of TG1 bacteria harbouring representative amounts of all the sublibraries by the addition of helper phage M13KO7. The phages were recovered from the supernatant by precipitation with a 1/5 volume 20% PEG in 2.5 M NaCl. The precipitated phages displaying antibodies were resuspended in PBS and stored at -70°C in 15% glycerol.

**Antibody selection by panning**

Immunotubes (Nunc Maxisorp) were coated overnight at 4°C with 100 µg/ml of the relevant protein or conjugated hapten dissolved in PBS. For selections on virus particles, Nunc Polysorp tubes were coated with 20 µg/ml of purified virus. All subsequent panning steps were performed at room temperature. The tubes were blocked for 1 h with 2% fat free milk powder (MP). After washing twice with PBS, approximately 5 x 10^12 library phage particles that had been preincubated for 30 min in 2% MP and 0.1% Tween-20 were added to each immunotube. Tubes were first rotated for 30 min before a stationary incubation of 90 min and then washed 20 x with PBS containing 0.1% Tween 20 (PBS/T) followed by a further 20 washes with PBS. Phage displayed antibodies were released by incubating for 10 min with 1.0 ml 100 mM triethylamine (pH 12). The eluate was neutralised by the addition of 0.5 ml 1 M TRIS-HCl (pH 7.4). The neutralised eluate was used to reinfact exponentially growing TG1 cells prior to plating on TYE plates containing 2% glucose and 100 µg/ml ampicillin. After an overnight incubation at 30°C the bacteria were collected and the phagemids rescued by the addition of M13KO7 helper phage (helper phage:bacteria = 20:1). Four such rounds of selection were usually performed. To screen monoclonal phage antibodies, individual clones were rescued by transferring inocula from bacterial colonies to the wells of sterile 96 well tissue culture plates containing 100 µl/well 2x TY A/G. Bacteria were grown overnight at 30°C with shaking at 250 RPM. The next day, a 96 well inoculation device (Sigma: Cat. No R-2508) was used to transfer cells from the master plate to a fresh plate that contained 150 µl 2x TY A/G per well. After a 2.5 h incubation at 250 RPM and 37°C, a 50 µl volume of 2x TY A/G that contained 2 x 10^9 pfu M13KO7 was added to each well. The plate was incubated at 37°C for 30 min without shaking. After centrifugation for 10 min at 600 x g the supernatant fluids were removed and replaced with 150 µl of 2 X TY that contained 100 µg/ml ampicillin and 25 µg/ml kanamycin. The plate was then incubated overnight at 30°C and 250 RPM. After centrifugation for 10 min at 600 x g, the supernatant fluids containing phage displayed antibodies were collected for testing in ELISA. To screen for monoclonal soluble scFvs, colonies were grown overnight in microtitre plates as above. Cells were then inoculated into wells containing 100 µl of 2x TY A/G, with the glucose concentration decreased to 0.1%. The cells were incubated at 37°C, with shaking, for 3 h after which 50 µl of 2x TY that contained 100 µg/ml ampicillin and 3 mM isopropyl-β-D-thiogalactopyranoside was added to each well. After incubating for a further 16 h at 30°C and 250 RPM the plates were centrifuged as above and the supernatant fluids were tested in ELISA.

**Polyclonal phage ELISA**

Immunoplates (Nunc Polysorp or Maxisorp) were coated overnight at 4°C with 50 µl/well of the relevant antigens suspended in PBS. Subsequent steps were performed at room temperature. Blocking was for 1 h with 300 µl/well of 2% MP in PBS. Phage displayed antibodies were concentrated 25 x by PEG precipitation and then diluted 1/100 prior to mixing with an equal volume of PBS containing 4% MP and 0.2% Tween 20. After three washes with PBS/T, the wells were incubated for 2 h with 50 µl/well of the phage displayed antibodies. The plate was washed three times and incubated for 1 h with 50 µl/well of an HRP/anti-M13 mAb conjugate (Amersham) diluted 1/5000 in PBS/T containing 2% MP. After a final wash, 50 µl/well of chromogen consisting of 1 mg/ml o-phenylene diamine and 0.5 µl/ml of a 30% (v/v) hydrogen peroxide in 0.1 M citrate buffer (pH 4.5) was added. Absorbance was monitored at 450 nm with the final reading being
taken at 492 nm after stopping the reaction with an equal volume of 2 N H₂SO₄.

**Monoclonal fusion phage and scFv ELISAs**
The protocol described above was used to show binding of individual scFvs fused to phage particle clones, except that the supernatant fluids from centrifuged microtitre plates were diluted 1:1 with PBS containing 2% Tween 20 and 4% MP. For selecting individual soluble scFvs, the detergent was omitted from the diluent for this and all subsequent steps. Bound phage displayed scFvs were detected by incubating for 1 h with 50 µl/well of 100 ng/ml mAb B62-FE2 in PBS/T that contained 2% MP followed by incubation for 1 h with 50 µl/well of HRP anti-mouse conjugate diluted 1/1000 in the same buffer. The mAb 9E10 which recognises the c-myc epitope tag was used when detecting soluble scFvs.

**DNA sequencing**
Phagemid DNA was isolated by means of a QIAprep Spin Miniprep Kit (QIAGEN) from 5 ml overnight cultures of single clones grown at 30°C and 250 rpm in 2x TY A/G. Primers OP52 and M13 rev were used (Table 1). Automated sequencing was done by the Molecular Biology Division, Onderstepoort Veterinary Institute. Sequences were analysed using Staden [47] and Wisconsin GCG [48] software packages.

**Inhibition ELISA**
A Polysorp (Nunc) microtitre plate was coated overnight at 4°C with 50 µl/well of 10 µg/ml BTV-10 in PBS and blocked as above. Blocking and washing steps were as before except that all incubations were at 37°C. After blocking, the plate was incubated for 1 h with 50 µl/well of the different sera diluted 1/9 in PBS containing 2% MP followed by an incubation of 1 h with 50 µl/well of phage antibody H2. PEG precipitated phages were first diluted in PBS to the pre-precipitation volume and then mixed 1:1 with PBS containing 4% MP and 0.2% Tween 20. Phage antibodies were detected using the pVIII-specific mAb with PBS containing 4% MP and 0.2% Tween 20. Phage PBS to the pre-precipitation volume and then mixed 1:1 subsequent steps from the addition of antibody B62-FE2 onwards were done as described for the inhibition ELISA, but the incubation times were shortened to 45 minutes.

**Expression and purification of soluble scFvs**
Individual bacterial clones were grown overnight in 2x TY A/G at 37°C. A dilution of 1/100 was made in the same medium and the bacteria were allowed to grow until the OD₆₀₀ reached a value of 0.9. The cells were collected by centrifugation and resuspended in a one-fifth volume of 2x TY containing 100 µg/ml ampicillin and 1 mM IPTG. After overnight incubation at 30°C, followed by centrifugation, scFvs were affinity-purified from the supernatant fluid using an anti-c-myc tag mAb. Six milligrams of mAb 9E10 IgG was immobilised on AminoLink Plus gel (Pierce) according to the manufacturer’s instructions. Medium containing the scFvs was passed over the column at least three times. After washing with 14 ml PBS, the bound scFvs were eluted with 5 ml 100 mM triethylamine and neutralised with 2.5 ml 1 M Tris pH 7.4. The eluted scFvs were concentrated by centrifugation in an Ultrafree Biomax unit (10K NMWL, Millipore) to approximately 300 µl. The concentration was determined spectrophotometrically with an A₂₈₀ of 1.0 corresponding to 0.7 mg/ml scFv and 1 mg/ml = 40 nM scFv.

**Surface plasmon resonance**
Kinetic binding constants were determined by surface plasmon resonance using a BIACORE X instrument (BIACORE, Uppsala, Sweden). Experiments were performed at 25°C using HBS-EP running buffer (10 mM HEPES pH 7.4, 150 mM NaCl, 3 mM EDTA, 0.005% surfactant P20) throughout. Bound scFvs were removed with 10 µl of 0.1 M glycine pH 2.5. Fluorescein-biotin (Sigma) was diluted in PBS to 10 pg/ml and allowed to bind to the surface of a streptavidin coated chip (Biacore). A blank flow cell was used as a reference surface. The immobilised hapten produced a signal of 12 RU. Anti-fluorescein scFvs ranging from 0.2 to 3.3 nM diluted in HBS-EP were injected over the chip at a flow rate of 30 µl/min for 70 seconds and allowed to dissociate for the same time. Horse heart cytochrome C (Sigma) was covalently bound to the dextran surface of a CM5 chip via its primary amine groups (BIAapplications handbook, BIACORE). A volume of 35 µl of cytochrome C (10 µg/ml diluted in 10 mM acetate buffer, pH 5.5) was injected and unreacted ester groups were blocked with 1 M ethanolamine-HCl, pH 8.5. These conditions resulted in 3,200 RU being immobilised. In the control flow cell 2,000 RU of chicken egg lysozyme was immobilised under the same conditions. Two different batches of anti-cytochrome C scFvs were injected at concentrations ranging from 2.9 nM to 17 PM. KLH was similarly immobilised using 35 µl of the protein at a concentration of 15 µg/ml in 10 mM acetate buffer, pH 4.5. After blocking unreacted groups, 10 µl of 25 mM NaOH was injected to remove unbound KLH. This resulted in 10,523 RU being bound. The second flow cell was left empty. Again two different batches of anti-KLH scFvs were injected, at concentrations ranging from 0.5 nM to 10 nM.
All kinetic analyses were done with BIAevaluation software according to the 1:1 Langmuir model using values obtained after subtracting the reference signal.

**Abbreviations**

AHSV African horsesickness virus  
BSA bovine serum albumin  
BTV bluetongue virus  
CDR complementarity determining region  
CMV cucumber mosaic virus  
CYT cytochrome C  
D diversity (region of immunoglobulin gene)  
EDC N-ethyl-N’-(dimethylaminopropyl) carbodiimide  
F-BSA fluorescein conjugated to bovine serum albumin  
H heavy (chain)  
h hour  
HRP horseradish peroxidase  
J joining (region of immunoglobulin gene)  
KLH Keyhole limpet haemocyanin  
L light (chain)  
mAb monoclonal antibody  
min minute  
MP fat free milk powder  
NHS N-hydroxysuccinimide  
N-BSA 4-hydroxy-3-iodo-5-nitrophenylacetic acid conjugated to bovine serum albumin  
PBS/T PBS containing 0.1% Tween 20  
pfu plaque-forming units  
RPM revolutions per minute  
RU resonance units (in BIACORE analysis)  
scFv single chain variable fragment  
TEL turkey egg lysozyme  
U unit (of enzyme)  
V variable (region of immunoglobulin gene)  
2xTY A/G 2xTY supplemented with 100 µg/ml ampicillin and 2% glucose

**Authors’ contributions**

WvW helped conceptualise the study and was largely responsible for the physical construction and evaluation of the library. TM and CM assisted in library construction, screening and evaluation by ELISA. FJ and JF were responsible for identifying, cloning and purifying the scFvs used in the BIACORE analysis. JF was responsible for bioinformatics and was assisted by DM in carrying out the kinetic analyses. DHduP conceived the project, participated in the design of the library, supervised all stages of the study and wrote the major portion of the manuscript. The authors have read and approved the final manuscript.

**Acknowledgements**

This work was supported by the Innovation Fund of the South African Department of Arts, Culture, Science and Technology. We thank the Medical Research Council (Cambridge, United Kingdom) for the pHEN display vector.
