Analyzing Gender Representation in Multilingual Models

Anonymous ACL submission

Abstract

Multilingual language models were shown to allow for nontrivial transfer across scripts and languages. In this work, we study the structure of the internal representations that enable this transfer. We focus on the representations of gender distinctions as a practical case study, and examine the extent to which the gender concept is encoded in shared subspaces across different languages. Our analysis shows that gender representations consist of several prominent components that are shared across languages, alongside language-specific components. The existence of language-independent and language-specific components provides an explanation for an intriguing empirical observation we make: while gender classification transfers well across languages, bias mitigation interventions trained on a single language do not transfer easily to others.

1 Introduction

Pretrained models of contextualized representations (Peters et al., 2018; Devlin et al., 2019; Liu et al., 2020) are known in their ability to capture both explicit and implicit information during training. A special case of these models are multilingual models (Devlin et al., 2019; Conneau et al., 2020), which are pretrained with texts in multiple languages. These models were shown to induce the emergence of similar representations in different languages, a phenomenon that was put to use for transfer between languages in end-tasks (Pires et al., 2019; Muller et al., 2020; Gonen et al., 2020).

However, the underlying mechanism is still not clear, and we do not know yet the full extent to which the representations of these models share information across languages.

The rise of pretrained models has been accompanied with growing concern regarding sensitive information they might encode, e.g. gender or ethnic distinctions. Pretrained language models were shown to be sensitive to gender information, both when it is explicitly stated in texts, as well as when it can be inferred from implicit information (Zhao et al., 2019; May et al., 2019). We still lack a complete understanding of what the model captures, and the ways to control and change the information in this context as well.

In this work, we aim to shed light on the way human-interpretable concepts, such as gender, are represented by multilingual models, and whether they are encoded in a language-dependant way. In a series of experiments, we uncover a seemingly surprising finding: gender-identification ability is highly transferable across languages (section 4.1) but neutralizing gender identification is not (section 4.2). While these two findings may seem contradictory at first glance, this is explained by several levels of gender marking: both cross-lingual and language-specific (section 5).

We start our analysis by training gender classifiers and examining their ability to transfer across languages. We then proceed to identifying "gender subspaces" — subspaces that encode gender — in each language, with the goal of understanding which information is language-specific, and which is shared across languages. Following recent work on linear interventions (Ravfogel et al., 2020; Elazar et al., 2021; Ravfogel et al., 2021), we take an “amnesic” approach: we study the extent to which neutralizing the gender subspace in one language interferes with gender prediction in another language. Finally, we analyze the similarity in the gender-encoding components across languages.

We find that while linear probes for gender transfer well between languages — that is, a gender classifier that is trained on one language predicts gender well in another language, the linear bias mitigation procedure we employ fails to transfer. A deeper analysis reveals a fine-grained organization of the gender-encoding subspaces across languages: they are spanned by a few main directions, which are largely similar across languages; but in addi-
tion to these directions, there are other directions that are language-specific. The existence of several similar directions explains the high degree of transferability of linear gender classifiers across languages, while the existence of a large amount of language-specific information explains the inability to efficiently mitigate bias in one language based on another language’s representation.

The code is attached to the submission and will be available upon publication, allowing full replication of the results in the paper.

2 Related Work

Multilingual Representation Analysis Pires et al. (2019) begin a line of work that studies mBERT’s representations and capabilities. They inspect the model’s zero-shot transfer abilities using different probing experiments, and propose a way to map sentence representations in different languages, with some success. Karthikeyan et al. (2020) further analyze the properties that affect zero shot transfer of bilingual BERTs. Wu and Dredze (2019) perform transfer learning from English to 38 languages, on 5 different downstream tasks and report good results. Wang et al. (2019) learn alignment between contextualized representations, and use it for zero shot transfer. Dufter and Schütze (2020) make an attempt to control different aspects of mBERT and identify those that contribute the most to its transfer ability.

Beyond focusing on zero-shot transfer abilities, an additional line of work studies the representations of mBERT and the information it stores. Using hierarchical clustering based on the CCA similarity scores between languages, Singh et al. (2019) are able to construct a tree structure that faithfully describes relations between languages. Chi et al. (2020) learn a linear syntax-subspace in mBERT, and point out to syntactic regularities in the representations that transfer across languages. In Cao et al. (2019), the authors define the notion of contextual word alignment and show improvement in zero-shot transfer after fine-tuning accordingly. In Libovický et al. (2020), the authors assume that mBERT’s representations have a language-neutral component, and a language-specific component and provide an experimental setting to partially support this assumption. Finally, in Gonen et al. (2020), the authors propose an explicit decomposition of the representations to language-encoding and language-neutral components, and also demonstrate that implicit word-level translations can be easily distilled from the model when exposed to the proper stimuli.

Unlike previous works, we pay attention specifically to how gender is manifested in the representations, as a case study for the analysis of a concrete societal property. We do that by focusing on the information included in the representations themselves, rather than on downstream tasks.

Gender Representation in Multilingual Models

To the best of our knowledge, no previous work focuses on the way gender is represented in multilingual models and the extent to which such representations are shared across languages.

Some work has been done on identifying and mitigating gender bias in languages other than English (Zhou et al., 2019; Bartl et al., 2020). Gonen et al. (2019) identify and debias a new type of gender bias, unique to gender-marking languages. Williams et al. (2021) look at the relationships between the grammatical genders of inanimate nouns and their co-occurring adjectives and verbs. In Zmigrod et al. (2019), the authors suggest a method for converting between masculine-inflected and feminine-inflected sentences in morphologically rich languages, and use them for counterfactual data augmentation in order to reduce gender stereotyping.

Zhao et al. (2020) analyze gender bias in multilingual word embeddings, and evaluate it intrinsically and extrinsically. They point to several factors that influence the gender bias in multilingual embeddings, among which are the pretrained monolingual word embeddings, and the alignment method used. Additionally, Liang et al. (2020) focus on contextualized embeddings, analyze the gender representation in BERT, and also put efforts into English-Chinese cross lingual debiasing. Finally, Bansal et al. (2021) focus on Indian languages when debiasing multilingual embeddings.

3 Datasets and Multilingual Representations

For our experiments we use the BiosBias Dataset (De-Arteaga et al., 2019), the Multilingual BiosBias Dataset (Zhao et al., 2020) and the multilingual BERT model (mBERT, (Devlin et al., 2019)) as detailed below.

Multilingual Gender Data. De-Arteaga et al. (2019) collected the English BiosBias dataset, a
set of short-biographies written in third person, and annotated by perceived gender. To do so they identified online biographies, written in English, from Common Crawl, by filtering for lines that match a pattern of a name and an occupation. Gender is labeled using heuristics, based on names and pronouns. In their work, they have demonstrated that profession classifiers trained on this dataset condition on the gender concept, resulting in fairness issues. Zhao et al. (2020) evaluate the bias in cross-lingual transfer settings, for which they created the Multilingual BiosBias (MLBs) Dataset which contains a similar set of biographies in three additional languages: French, Spanish and German. Note that these are not translations of the English portion, but are crawled independently with a similar method.

For our experiments we use both datasets to have English, Spanish and French data. These were not available online, so we used the scripts the authors provide for crawling the dataset ourselves. To avoid noisy results, we filter out examples of professions with less than 500 occurrences. Table 1 describes the statistics of the dataset in all languages. Note that the dataset is not balanced for male/female, especially for French and Spanish (same as before our filtering), and that the English portion is significantly larger. Following (De-Arteaga et al., 2019), we split randomly into Train/Dev/Test sets with ratio of 65%/10%/25%, while ensuring that the main classes (professions) are balanced across them. Unfortunately, more languages were not available at this point, so we opt to use English, French and Spanish.

| Language | Examples | Female | Male | Majority | # Prof |
|----------|----------|--------|------|----------|--------|
| EN       | 255682   | 118344 | 137338 | 53.71    | 28     |
| FR       | 42773    | 12196  | 30577 | 71.49    | 19     |
| ES       | 46931    | 12867  | 34064 | 72.58    | 27     |

Table 1: Statistics of the MLBs dataset.

Multilingual Representations. To study the representation of the gender concept in a multilingual setting, we use multilingual BERT (mBERT3, 110M parameters) (Devlin et al., 2019). For each example in the dataset, we extract its representation from mBERT by averaging the representations in context of all the tokens in the paragraph.

4 Gender Representation across Language

4.1 Transfer of Gender Probes

As a first step in understanding gender representation in multilingual models, we start with a basic experiment that aims to evaluate the extent to which gender is represented similarly across languages.

We train a linear classifier (Logistic Regression using SKlearn4 with default parameters) for gender classification in a SOURCE language, and use it as is to predict gender in a TARGET language. The training is done over the mBERT representations of the training examples.

The results, presented in Table 2, indicate that gender classifiers transfer very well across languages, with only a slight degradation in performance when applied in a different language. For example, the accuracy of the English gender classifier is 99.27%, but when the French or Spanish classifiers are used to predict gender in English data, the accuracy is 98.10% and 97.29%, respectively. The same trend is observed for the French and Spanish datasets. These results suggest that gender information is linearly accessible in mBERT representation and is shared between languages.

| Language | EN train | FR train | ES train |
|----------|----------|----------|----------|
| EN test  | 99.27    | 98.10    | 97.29    |
| FR test  | 95.97    | 97.50    | 94.61    |
| ES test  | 84.04    | 84.10    | 85.97    |

Table 2: Accuracy of gender classification across languages with linear classifiers. Rows represent the language of the prediction data, columns represent the language in which the classifier was trained.

4.2 Cross-lingual Linear Bias Mitigation

The experiment described above suggests some gender components are shared between languages. As bias mitigation techniques focus on the removal of bias information, a natural question that arises is whether mitigation efforts focused on one language would transfer to another. This question is important for two reasons. First, if possible, this has a potential practical utility – e.g., enabling bias mitigation in low-resource languages, for which train-

3https://scikit-learn.org/stable/
ing data is scarce. Second, the degree of success in transfer of bias mitigation efforts is a complementary way to assess whether the representation of gender is indeed multilingual.

Previous experiments on removing the gender concept from neural representations show encouraging results in-language for English. These are done using INLP (Ravfogel et al., 2020), an existing approach for the identification and neutralization of “concept subspaces”, e.g. the gender concept. In these experiments, Ravfogel et al. (2020) show they manage to neutralize the ability of linear probes to recover gender information from the representations. In light of the above results that show high quality transfer of gender classifiers across languages, we leverage the INLP method, and attempt to remove gender information from the representations across languages.

Iterative Null-space Projection (INLP) INLP (Ravfogel et al., 2020) aims to remove linearly-decodable information from vector representations.

INLP constructs a concept subspace iteratively, by finding directions of the relevant concept (e.g. gender) and neutralizing them by projecting the representations onto their nullspace. On each iteration, a classifier is trained on the representations, which were projected onto the nullspace of the previous classifiers, i.e., is optimized to identify residual information which was not captured by previous directions. This iterative procedure relies on the intuition that if one wants to find a subspace whose neutralization hinders the ability to predict some concept, one can first identify directions that encode that concept, and neutralize them.

Formally, given a dataset of representations $X$ (in our case, mBERT representations) and annotations $Z$ for the information to be removed (gender) the method renders $Z$ linearly unpredictable from $X$. It does so by iteratively training linear predictors $w_1, \ldots, w_n$ of $Z$, calculating the projection matrix onto their nullspace $P_N := P_N(w_1), \ldots, P_N(w_n)$, and transforming $X \leftarrow P_N X$. By the nullspace definition, this guarantees $w_i P_N X = 0, \forall w_i$, i.e., the features that $w_i$ uses for gender prediction are neutralized. Note that the guarantee is only with respect to linear separation.

While the nullspace $N(w_1, \ldots, w_n)$ is a subspace in which $Z$ is not linearly predictable, the complement rowspace $R(w_1, \ldots, w_n)$ is a subspace of the representation space $X$ that corresponds to the property $Z$. In our case, this subspace is the gender subspace. As part of the analysis in this work, we utilize INLP in two complementary ways: (1) we use the null-space projection matrix $P_N$ to zero out the gender subspace, in order to render the representations gender-neutral,\(^5\) this projection is onto the gender-neutral subspace; and (2) we use the rowspace projection matrix $P_R = I - P_N$ to project mBERT representations onto the gender subspace, keeping only the parts that are useful for gender prediction.

**Method** We start by training INLP in one language (En, Fr, Es) and identifying the complementing subspaces: the gender-neutral subspace – nullspace, and the gender subspace – rowspace (for later use, see Section 5). We then neutralize that subspace in another language. Finally, we examine the influence of this intervention and assess the effect of gender information reduction.

We run INLP with the objective of identifying the gender, with SVM classifiers (using SKLearn) for 100 iterations. We use the average representations (averaging over the representations in context of all tokens) of the training paragraphs.

**Results** Tables 3 and 4 depict the results of gender and profession prediction (with Logistic Regression) in each language (rows) before and after applying INLP (each column stands for a different language for training INLP). We get that in-language, the accuracy of gender prediction drops to majority after applying INLP, while profession classification is only slightly hurt. For example, for English we get gender prediction accuracy of 53.7 compared to 99.3 before using INLP, and profession prediction accuracy of 78.1 compared to 79.9 before INLP. However, across languages, there is virtually no effect, both for gender prediction and profession prediction. For example, English gender and profession predictions drop from 99.3 to 98.1 and from 79.9 to 79.5, respectively, after applying Spanish INLP.

Interestingly, the largest drops in performance of profession classification due to application of INLP are in-language. This can be explained by the inherent correlations between gender and profession signals – removing gender information hurts the ability to predict the profession in the same language. This is not the case across-language since,

\(^5\)to the extent that gender is indeed encoded in a linear subspace, and that INLP finds this subspace.
To define the term "partial sharing" formally, we represent gender in each language as a collection of linear directions that together span the gender subspace of that language. This collection of directions can be identified using INLP – when training INLP on a specific language, we get a sequence of directions that together span the gender subspace of that language. This collection of directions fully shared across languages, fully disjoint, or split (i.e. some are shared between languages and some are disjoint)?

Intuitively, when projecting representations on the gender subspace, we expect all the information relevant to gender prediction to be kept in the projected representations. Similarly, when projecting representations on the gender-neutral subspace, we expect the opposite – that the projected representations will not include any gender-related information.

With this intuition we seek to determine the extent to which gender information is shared between languages by comparing their gender subspaces (with similar gender subspaces indicating high amount of shared information). To quantify the shared information, we carefully compare the different directions, taking their significance into account. This process is explained in detail below.

**Method** In this experiment, we make use of our projection mechanism as a way to control the information included or excluded from the representations. We compare the original mBERT representations of the training data before and after projecting them on the learned gender and gender-neutral subspaces of the different languages (see “ Compared Representations” below). For each set of compared representations we perform PCA (principal component analysis) and look at the explained variance.
of each PCA direction (i.e., the ratio between its variance and the total variance of the data), from large to small – this tells us the variance in the representations. When comparing the explained variance before and after a projection, we are able to quantify the information that was lost by that projection.

We take English and French as our running example. We perform two projections subsequently and compare the representations before, in between and after the projections: the first projection is on the English gender subspace – this preserves the gender directions in English; The second projection is on the French gender-neutral subspace – this eliminates the gender directions in French. In case there are no shared gender directions between the two languages: the representations after the first projection encode gender information in English, and no information is lost when further eliminating French gender directions – we expect the plots after the first and the second projections to be identical. Conversely, we expect that full sharing of gender directions between the languages will result in zero variance after the two projections – the first projection keeps only English gender directions, and these are eliminated when eliminating the (same) French gender directions (by projecting on the French gender-neutral subspace).

Compared Representations We start by training INLP and obtaining a collection of 100 gender directions in each language (EN FR, ES), from the most prominent to the least prominent one. We use 100 dimensions regardless of what was needed for INLP to converge, so as to be consistent across languages and avoid artifacts due to the number of dimensions. We compare different sets of representations as detailed below, for English vs. French, English vs. Spanish and French vs. Spanish (the explanation below is assuming English vs. Spanish):

- **ORIG**: Original representations (in English).
- **ENGENDER**: ORIG projected on the English gender subspace (rowspace).
- **ENRAND**: ORIG projected with a random matrix with the same dimensions as the EnGender matrix (for comparison).
- **ENGENDER+FRNEUTRAL**: ENGENDER projected on the French gender-neutral subspace (nullspace).
- **ENGENDER+FRRAND**: ENGENDER projected on a random matrix with the same dimensions as the French gender-neutral matrix (for comparison).
- **ENGENDER+ENNEUTRAL**: ENGENDER projected on English gender-neutral subspace (nullspace).

Figure 1: Explained variance of PCA of different representations, for all three language pairs.

**Result Analysis** The results are shown in Figure 1. The plots support our initial hypothesis: indeed, we get that gender directions are shared between languages but only partially. Focusing on English vs. French, we can see that as ex-
pected, the curve of EN\textsc{Gender}+Fr\textsc{Neutral} (cyan) is lower than that of EN\textsc{Gender} (blue), implying that there are shared gender directions between English and French. Recall that projecting the representations on the English gender subspace (EN\textsc{Gender}) keeps mainly English gender directions, and then projecting on French gender-neutral subspace (EN\textsc{Gender}+Fr\textsc{Neutral}) removes French gender directions. If no directions are shared, this should result with similar values for both EN\textsc{Gender} and EN\textsc{Gender}+Fr\textsc{Neutral}. However, the sharing is only partial: if all directions are shared, we expect EN\textsc{Gender}+Fr\textsc{Neutral} to be zero (similar to EN\textsc{Gender}+En\textsc{Neutral}), which is not the case.

Controls The EN\textsc{Gender}+Fr\textsc{Rand} projections are intended as reference for EN\textsc{Gender}+Fr\textsc{Neutral}. If there are shared gender directions between English and French, we expect the curve of EN\textsc{Gender}+Fr\textsc{Neutral} to be lower than that of EN\textsc{Gender}+Fr\textsc{Rand}, since by projecting on the French gender-neutral subspace we are expected to lose more information than with a random projection with the same dimensions. In Figure 1a we see that the curve of EN\textsc{Gender}+Fr\textsc{Neutral} (cyan) is indeed lower than that of EN\textsc{Gender}+Fr\textsc{Rand} (pink), indicating that the loss of information is not due to random shared directions.

Note also that the curve of EN\textsc{Gender} (blue) is significantly higher than that of EN\textsc{Rand} (red). We hypothesize that this is due to the fact that gender is usually dominant in natural texts, especially in a dataset that includes information about individuals, as this one. Thus, keeping only gender information by projecting on the English gender subspace keeps a large portion of the information, compared to projecting on arbitrary directions of the same dimension.

Another sanity check is obtained by projecting EN\textsc{Gender} on the English gender-neutral subspace (EN\textsc{Gender}+En\textsc{Neutral}), this should, by definition, result in a 0 line, which is indeed the case (orange).

5.2 Similarities of Dominant Directions

In the previous section we established the hypothesis that some gender directions are shared between languages while others are language-specific. Now, we turn to perform a more fine-grained analysis where we look at the specific directions in the different languages.

We look at the first 100 classifiers (trained during INLP) in two languages, and compute all pairwise cosine similarities between them (across language). This leads us to a surprising result – only the first classifiers in both languages are similar to each other, while the rest are not: we get that the 3 highest similarities are between the first En classifier and the first Fr classifier, between the second En classifier and the second Fr classifier, and between the third En classifier and the third Fr classifier, with values of 0.777, 0.597 and 0.453, respectively. The average absolute cosine similarity among all pairwise similarities of the first 100 classifiers in English and French is 0.037. Interestingly, the more dominant directions are those that are shared cross-lingually, while the less predictive directions are those that are language specific.

Figure 2 depicts the similarities of the $i$th classifiers for the two languages (English-French, English-Spanish and French-Spanish). We also plot the gender classification accuracy in-language for reference. This result completes the picture and serves as an explanation for the extremely high quality transfer of gender classification across languages – the most dominant directions that represent gender in each language are cross-lingual, which enables high accuracy in zero-shot transfer of linear gender classifiers across languages. However, less dominant gender directions are language specific, but are predictive enough so as to prevent gender neutralization across languages using INLP.

5.3 Accuracy across Language

Finally, we also look at the performance of each classifier (trained during INLP) across languages. In Figure 3, we depict the gender prediction accuracy in-language and across-language. We consistently get that the performance of the first 2-3 classifiers trained in-language and also across-language is relatively similar, with a significant divergence between in-language and cross-language trainings for the subsequent classifiers. This matches the results of the previous experiment which shows high similarity only between the first classifiers in the different languages.

6 Conclusion

As part of the efforts to better understand the underlying mechanism of multilingual modeling, we focus in this work on the way gender is represented...
across languages. We analyze and quantify the extent to which gender information is shared across English, French and Spanish.

We find that on the one hand, gender prediction transfers very well across languages: training a linear classifier on English data yields a high quality classifier for French and Spanish as well (true for all three languages in both directions). On the other hand, our attempt to neutralize gender information across languages using INLP, which was shown to work in English, was unsuccessful.

We show that these two results are compatible, and together they shed light on the structure of the representation space: we provide experimental evidence that the most salient directions are shared between languages (which enables good transfer of the classifiers), while others are unique per language (which interferes with gender removal across languages). The key observation is that a single “good” direction of the gender subspace in one language is enough for cross-lingual gender prediction transfer, while transfer of gender neutralization requires all directions to be shared, otherwise, the remaining ones can be used to recover gender information after the removal of the shared ones.
7 Ethical Considerations

Gender bias mitigation has attracted a lot of attention as a practical and socially important field of study. This paper contributes to this effort by studying the internal organization of gender representations. We note that gender and bias are complicated and multi-faceted constructs. When studying gender bias in neural models, we unavoidably rely on a narrow notion of gender, as reflected in several annotated datasets. As such, we see this study as a preliminary attempt that is based on a relatively narrow concept of gender bias, that does not reflect the subtle ways by which social gender is manifested. We advise for caution when applying the conclusions of this study to other notions of gender or other definitions of bias.

We acknowledge that gender is not a binary property. Due to lack of existing resources, we use binary gender as a rough approximation of reality. We hope to account for this in future work.
