Abstract

In this paper we address three different computer vision tasks using a single multiscale convolutional network architecture: depth prediction, surface normal estimation, and semantic labeling. The network that we develop is able to adapt naturally to each task using only small modifications, regressing from the input image to the output map directly. Our method progressively refines predictions using a sequence of scales, and captures many image details without any superpixels or low-level segmentation. We achieve state-of-the-art performance on benchmarks for all three tasks.

1. Introduction

Scene understanding is a central problem in vision that has many different aspects. These include semantic labels describing the identity of different scene portions; surface normals or depth estimates describing the physical geometry; instance labels of the extent of individual objects; and affordances capturing possible interactions of people with the environment. Many of these are often represented with a pixel-map containing a value or label for each pixel, e.g. a map containing the semantic label of the object visible at each pixel, or the vector coordinates of the surface normal orientation.

In this paper, we address three of these tasks, depth prediction, surface normal estimation and semantic segmentation — all using a single common architecture. Our multiscale approach generates pixel-maps directly from an input image, without the need for low-level superpixels or contours, and is able to align to many image details using a series of convolutional network stacks applied at increasing resolution. At test time, all three outputs can be generated in real time (~30Hz). We achieve state-of-the-art results on all three tasks we investigate, demonstrating our model’s versatility.

There are several advantages in developing a general model for pixel-map regression. First, applications to new tasks may be quickly developed, with much of the new work lying in defining an appropriate training set and loss function; in this light, our work is a step towards building off-the-shelf regressor models that can be used for many applications. In addition, use of a single architecture helps simplify the implementation of systems that require multiple modalities, e.g. robotics or augmented reality, which in turn can help enable research progress in these areas. Lastly, in the case of depth and normals, much of the computation can be shared between modalities, making the system more efficient.

2. Related Work

Convolutional networks have been applied with great success for object classification and detection [19, 12, 30, 32, 34]. Most such systems classify either a single object label for an entire input window, or bounding boxes for a few objects in each scene. However, ConvNets have recently been applied to a variety of other tasks, including pose estimation [36, 27], stereo depth [38, 25], and instance segmentation [14]. Most of these systems use ConvNets to find only local features, or generate descriptors of discrete proposal regions; by contrast, our network uses both local and global views to predict a variety of output types. In addition, while each of these methods tackle just one or two tasks at most, we are able to apply our network to three disparate tasks.

Our method builds upon the approach taken by Eigen et al. [8], who apply two convolutional networks in stages for single-image depth map prediction. We develop a more general network that uses a sequence of three scales to generate features and refine predictions to higher resolution, which we apply to multiple tasks, including surface normals estimation and per-pixel semantic labeling. Moreover, we improve performance in depth prediction as well, illustrating how our enhancements help improve all tasks.

Single-image surface normal estimation has been addressed by Fouhey et al. [10, 11], Ladicky et al. [21], Barron and Malik [3, 2], and most recently by Wang et al. [37], the latter in work concurrent with ours. Fouhey et al. match to discriminative local templates [10] followed by a global op-
timization on a grid drawn from vanishing point rays [11], while Ladicky et al. learn a regression from over-segmented regions to a discrete set of normals and mixture coefficients. Barron and Malik [3, 2] infer normals from RGB-D inputs using a set of handcrafted priors, along with illumination and reflectance. From RGB inputs, Wang et al. [37] use convolutional networks to combine normals estimates from local and global scales, while also employing cues from room layout, edge labels and vanishing points. Importantly, we achieve as good or superior results with a more general multiscale architecture that can naturally be used to perform many different tasks.

Prior work on semantic segmentation includes many different approaches, both using RGB-only data [35, 4, 9] as well as RGB-D [31, 29, 26, 6, 15, 17, 13]. Most of these use local features to classify over-segmented regions, followed by a global consistency optimization such as a CRF. By comparison, our method takes an essentially inverted approach: We make a consistent global prediction first, then follow it with iterative local refinements. In so doing, the local networks are made aware of their place within the global scene, and can use this information in their refined predictions.

Gupta et al. [13, 14] create semantic segmentations first by generating contours, then classifying regions using either hand-generated features and SVM [13], or a convolutional network for object detection [14]. Notably, [13] also performs amodal completion, which transfers labels between disparate regions of the image by comparing planes from the depth.

Most related to our method in semantic segmentation are other approaches using convolutional networks. Farabet et al. [9] and Couprie et al. [6] each use a convolutional network applied to multiple scales in parallel generate features, then aggregate predictions using superpixels. Our method differs in several important ways. First, our model has a large, full-image field of view at the coarsest scale; as we demonstrate, this is of critical importance, particularly for depth and normals tasks. In addition, we do not use superpixels or post-process smoothing — instead, our network produces fairly smooth outputs on its own, allowing us to take a simple pixel-wise maximum.

Pinheiro et al. [28] use a recurrent convolutional network in which each iteration incorporates progressively more context, by combining a more coarsely-sampled image input along with the local prediction from the previous iteration. This direction is precisely the reverse of our approach, which makes a global prediction first, then iteratively refines it. In addition, whereas they apply the same network parameters at all scales, we learn distinct networks that can specialize in the edits appropriate to their stage.

Most recently, in concurrent work, Long et al. [24] adapt the recent VGG ImageNet model [32] to semantic segment-
3. Model Architecture

Our model is a multi-scale deep network that first predicts a coarse global output based on the entire image area, then refines it using finer-scale local networks. This scheme is illustrated in Fig. 1. While our model was initially based upon the architecture proposed by [8], it offers several architectural improvements. First, we make the model deeper (more convolutional layers). Second, we add a third scale at higher resolution, bringing the final output resolution up to half the input, or 147 × 109 for NYUDepth. Third, instead of passing output predictions from scale 1 to scale 2, we pass multichannel feature maps; in so doing, we found we could also train the first two scales of the network jointly from the start, somewhat simplifying the training procedure and yielding performance gains.

Scale 1: Full-Image View The first scale in the network predicts a coarse but spatially-varying set of features for the entire image area, based on a large, full-image field of view, which we accomplish this through the use of two fully-connected layers. The output of the last full layer is reshaped into a 1/16-scale in its spatial dimensions by 64 features, then upsampled by a factor of 4 to 1/4-scale. Note since the feature upsampling is linear, this corresponds to a decomposition of a big fully connected layer from layer 1.6 to the larger 74 × 55 map; since such a matrix would be prohibitively large and only capable of producing a blurry output given the more constrained input features, we constrain the resolution and upsample. Note, however, that the 1/16-scale output is still large enough to capture considerable spatial variation, and in fact is twice as large as the 1/32-scale final convolutional features of the coarse stack.

Since the top layers are fully connected, each spatial location in the output connects to all the image features, incorporating a very large field of view. This stands in contrast to the multiscale approach of [6, 9], who produce maps where the field of view of each output location is a more local region centered on the output pixel. This full-view connection is especially important for depth and normals tasks, as we investigate in Section 7.1.

As shown in Fig. 1, we trained two different sizes of our model: One where this scale is based on an ImageNet-trained AlexNet [19], and one where it is initialized using the Oxford VGG network [32]. We report differences in performance between the models across all tasks, to measure the impact of model size in each.

Scale 2: Predictions The job of the second scale is to produce predictions at a mid-level resolution, by incorporating a more detailed but narrower view of the image along with the full-image information supplied by the coarse network. We accomplish this by concatenating the feature maps of the coarse network with those from a single layer of convolution and pooling, performed at finer stride (see Fig. 1). The output of the second scale is a 55x74 prediction (for NYUDepth), with the number of channels depending on the task. We train Scales 1 and 2 of the model together jointly, using SGD on the losses described in Section 4.

Scale 3: Higher Resolution The final scale of our model refines the predictions to higher resolution. We concatenate the Scale-2 outputs with feature maps generated from the original input at yet finer stride, thus incorporating a more detailed view of the image. The further refinement aligns the output to higher-resolution details, producing spatially coherent yet quite detailed outputs. The final output is half of the network input.

4. Tasks

We apply this same architecture structure to each of the three tasks we investigate: depths, normals and semantic labeling. Each makes use of a different loss function and target data defining the task.

4.1. Depth

For depth prediction, we use a loss function comparing the predicted and ground-truth log depth maps D and D*. Letting $d = D - D*$ be their difference, we set the loss to

$$L_{\text{depth}}(D, D^*) = \frac{1}{n} \sum_i d_i^2 - \frac{1}{2n^2} \left( \sum_i d_i \right)^2 + \frac{1}{n} \sum_i [(\nabla_x d_i)^2 + (\nabla_y d_i)^2]$$

(1)

where the sums are over valid pixels i and n is the number of valid pixels (we mask out pixels where the ground truth is missing). Here, $\nabla_x d_i$ and $\nabla_y d_i$ are the horizontal and vertical image gradients of the difference.

Our loss is similar to that of [8], who also use the $l_2$ and scale-invariant difference terms in the first line. However, we also include a first-order matching term $(\nabla_x d_i)^2 + (\nabla_y d_i)^2$, which compares image gradients of the prediction with the ground truth. This encourages predictions to have not only close-by values, but also similar local structure. We found it indeed produces outputs that better follow depth gradients, with no degradation in measured $l_2$ performance.

4.2. Surface Normals

To predict surface normals, we change the output from one channel to three, and predict the x, y and z components of the normal at each pixel. We also normalize the vector at each pixel to unit $l_2$ norm, and backpropagate through this normalization. We then employ a simple elementwise loss comparing the predicted normal at each pixel to the ground truth, using a dot product:

$$L_{\text{normals}}(N, N^*) = -\frac{1}{n} \sum_i N_i \cdot N_i^* = -\frac{1}{n} N \cdot N^*$$

(2)

where N and N* are predicted and ground truth normal vector maps, and the sums again run over valid pixels (i.e. those with a ground truth normal).
For ground truth targets, we compute the normal map using the same method as in Silberman et al. \cite{silberman2012indoor}, which estimates normals from depth by fitting least-squares planes to neighboring sets of points in the point cloud.

\subsection*{4.3. Semantic Labels}

For semantic labeling, we use a pixelwise softmax classifier to predict a class label for each pixel. The final output then has as many channels as there are classes. We use a simple pixelwise cross-entropy loss,

$$L_{\text{semantic}}(C, C^*) = -\frac{1}{n} \sum_i C_i^* \log(C_i)$$

where $C_i = e^{z_i} / \sum_s e^{z_i,s}$ is the class prediction at pixel $i$ given the output $z$ of the final convolutional linear layer 3.4.

When labeling the NYUDepth RGB-D dataset, we use the ground truth depth and normals as additional input channels. We convolve each of the three input types (RGB, depth and normals) with a different set of $32 \times 9 \times 9$ filters, then concatenate the resulting three feature sets along with the network output from the previous scale to form the input to the next. We also tried the “HHA” encoding proposed by \cite{hassner2018unsupervised}, but did not see a benefit in our case, thus we opt for the simpler approach of using the depth and $xyz$-normals directly. Note the first scale is initialized using ImageNet, and we keep it RGB-only. Applying convolutions to each input type separately, rather than concatenating all the channels together in pixel space and filtering the joint input, enforces independence between the features at the lowest filter level, which we found helped performance.

\section*{5. Training}

\subsection*{5.1. Training Procedure}

We train our model in two phases using SGD: First, we jointly train both Scales 1 and 2. Second, we fix the parameters of these scales and train Scale 3. Since Scale 3 contains four times as many pixels as Scale 2, it is expensive to train using the entire image area for each gradient step. To speed up training, we instead use random crops of size $74x55$. We first forward-propagate the entire image through scales 1 and 2, upsample, and crop the resulting Scale 3 input, as well as the original RGB input at the corresponding location. The cropped image and Scale 2 prediction are forward- and back-propagated through the Scale 3 network, and the weights updated. We find this speeds up training by about a factor of 3, including the overhead for inference of the first two scales, and results in about the same if not slightly better error from the increased stochasticity.

All three tasks use the same initialization and learning rates in nearly all layers, indicating that hyperparameter settings are in fact fairly robust to changes in task. Each were first tuned using the depth task, then verified to be an appropriate order of magnitude for each other task using a small validation set of 50 scenes. The only differences are: (i) The learning rate for the normals task is 10 times larger than depth or labels. (ii) Relative learning rates of layers 1.6 and 1.7 are 0.1 each for depth/normals, but 1.0 and 0.01 for semantic labeling. (iii) The dropout rate of layer 1.6 is 0.5 for depth/normals, but 0.8 for semantic labels, as there are fewer training images.

We initialize the convolutional layers in Scale 1 using ImageNet-trained weights, and randomly initialize the fully connected layers of Scale 1 and all layers in Scales 2 and 3. We train using batches of size 32 for the AlexNet-initialized model but batches of size 16 for the VGG-initialized model due to memory constraints. In each case we step down the global learning rate by a factor of 10 after approximately 2M gradient steps, and train for an additional 0.5M steps.

\subsection*{5.2. Data Augmentation}

In all cases, we apply random data transforms to augment the training data. We use random scaling, in-plane rotation, translation, color, flips and contrast. When transforming an input and target, we apply corresponding transformations to RGB, depth, normals and labels. Note the normal vector transformation is the inverse-transpose of the worldspace transform: Flips and in-plane rotations require flipping or rotating the normals, while to scale the image by a factor $s$, we divide the depths by $s$ but multiply the $z$ coordinate of the normals and renormalize.

\subsection*{5.3. Combining Depth and Normals}

We combine both depths and normals networks together to share computation, creating a network using a single scale 1 stack, but separate scale 2 and 3 stacks. Thus we predict both depth and normals at the same time, given an RGB image. This produces a 1.6x speedup compared to using two separate models.~\footnote{This shared model also enabled us to try enforcing compatibility between predicted normals and those obtained via finite difference of the predicted depth (predicting normals directly performs considerably better than using finite difference). However, while this constraint was able to improve the normals from finite difference, it failed to improve either task individually. Thus, while we make use of the shared model for computational efficiency, we do not use the extra compatibility constraint.}

\section*{6. Performance Experiments}

\subsection*{6.1. Depth}

We first apply our method to depth prediction on NYUDepth v2. We train using the entire NYUDepth v2 raw data distribution, using the scene split specified in the official train/test distribution. We then test on the common distribution depth maps, including filled-in areas, but constrained to the axis-aligned rectangle where there there is a valid depth map projection. Since the network output is a lower resolution than the original NYUDepth images, and excludes a small border, we bilinearly upsample our network outputs to the original 640x480 image scale, and extrapolate the missing border using a cross-bilateral filter. We compare our method to prior works Ladicky et al. \cite{ladicky2017semi}.
Karsh et al. [18], Baig et al. [1], Liu et al. [23] and Eigen et al. [8].

The results are shown in Table 1. Our model obtains best performance in all metrics, due to our larger architecture and improved training. In addition, the VGG version of our model significantly outperforms the smaller AlexNet version, reinforcing the importance of model size: this is the case even though the depth task is seemingly far removed from the classification task with which the initial coarse weights were first trained. Qualitative results in Fig. 2 show substantial improvement in detail sharpness over [8].

6.2. Surface Normals

Next we apply our method to surface normals prediction. We compare against the 3D Primitives (3DP) and “Indoor Origami” works of Fouhey et al. [10, 11], Ladicky et al. [21], and Wang et al. [37]. As with the depth network, we used the full raw dataset for training, since ground-truth normal maps can be generated for all images. Since different systems have different ways of calculating ground truth normal maps, we compare using both the ground truth as constructed in [21] as well as the method used in [31]. The differences between ground truths are due primarily to the fact that [21] uses more aggressive smoothing; thus [21] tends to present flatter areas, while [31] is noisier but keeps more details present. We measure performance with the same metrics as in [10]: The mean and median angle from the ground truth across all unmasked pixels, as well as the percent of vectors whose angle falls within three thresholds.

Results are shown in Table 2. The smaller version of our model performs similarly or slightly better than Wang et al., while the larger version substantially outperforms all comparison methods. Figure 3 shows example predictions. Note the details captured by our method, such as the curvature of the blanket on the bed in the first row, sofas in the second row, and objects in the last row.

6.3. Semantic Labels

6.3.1 NYU Depth

We finally apply our method to semantic segmentation, first also on NYU Depth. Because this data provides a depth channel, we use the ground-truth depth and normals as input into the semantic segmentation network, as described in Section 4.3. We evaluate our method on semantic class sets with 4, 13 and 40 labels, described in [31], [6] and [13], respectively. The 4-class segmentation task uses high-level category labels “floor”, “structure”, “furniture” and “props”, while the 13- and 40-class tasks use different sets of more fine-grained categories. We compare with several recent methods, using the metrics commonly used to evaluate each task: For the 4- and 13-class tasks we use pixel-wise and per-class accuracy; for the 40-class task, we also compare using the mean pixel-frequency weighted Jaccard index of each class, and the flat mean Jaccard index.

Results are shown in Table 3. We decisively outperform the comparison methods on the 4- and 14-class tasks. In the 40-class task, our model outperforms Gupta et al. ‘14 with both model sizes, and Long et al. with the larger size. Qualitative results are shown in Fig. 4. Even though our method does not use superpixels or any piecewise constant assumptions, it nevertheless tends to produce large constant regions most of the time.

Table 1. Depth estimation measurements. Note higher is better for top rows of the table, while lower is better for the bottom section.

Table 2. Surface normals prediction measured against the ground truth constructed by [21] (top) and [31] (bottom).

Table 3. NYU Depth

6.3.2 Scene Flow

We finally apply our method to optical flow estimation. We use the NYU Scene Flow dataset [32], which contains images of an indoor scene with both ground truth depth and optical flow. We evaluate our method on the NYU Scene Flow validation set, which consists of 40 images.

Results are shown in Table 4. Our model outperforms all comparison methods. Qualitative results are shown in Fig. 5. We also compare using the mean pixel-frequency weighted Jaccard index of each class, and the flat mean Jaccard index. Our method produces more accurate optical flow predictions, especially in regions with large motion.
Table 3. Semantic labeling on NYUDepth v2.

| Pixel Class | Class | Pixel Class | Class |
|-------------|-------|-------------|-------|
| Compte & al. [7] | 64.5 63.5 | Compte & al. [16] | 52.4 36.3 |
| Khan & al. [15] | 69.2 65.6 | Wang & al. [37] | 42.2 |

Table 6. Comparison of networks for different scales for depth, normals and semantic labeling tasks with 4 and 13 categories. Largest single contributing scale is underlined.

6.3.2 Sift Flow

We confirm our method can be applied to additional scene types by evaluating on the Sift Flow dataset [22], which contains images of outdoor cityscapes and landscapes segmented into 33 categories. We found no need to adjust convolutional kernel sizes or learning rates for this dataset, and simply transfer the values used for NYUDepth directly; however, we do adjust the output sizes of the layers to match the new image sizes.

We compare against Tighé et al. [35], Farabet et al. [9], Pinheiro [28] and Long et al. [24]. Note that Farabet et al. train two models, using empirical or rebalanced class distributions by resampling superpixels. We train a more class-balanced version of our model by reweighting each class in the cross-entropy loss; we weight each pixel by $\alpha_c = \text{median}\_\text{freq} / \text{freq}(c)$ where $\text{freq}(c)$ is the number of pixels of class $c$ divided by the total number of pixels in images where $c$ is present, and $\text{median}\_\text{freq}$ is the median of these frequencies.

Results are in Table 4; we compare regular (1) and reweighted (2) versions of our model against comparison methods. Our smaller model substantially outperforms all but Long et al., while our larger model performs similarly to Long et al. This demonstrates our model’s adaptability not just to different tasks but also different data.

6.3.3 Pascal VOC

In addition, we also verify our method using Pascal VOC. Similarly to Long et al. [24], we train using the 2011 train-
coarse Scale 1 for depth and normals, but the more local Scale 2 for the semantic tasks — however, this is only due to the fact that the depth and normals channels are introduced at Scale 2 for the semantic labeling task. Looking at the labeling network with RGB-only inputs, we find that the coarse scale is again the larger contributor, indicating the importance of the global view. (Of course, this scale was also initialized with ImageNet convolution weights that are much related to the semantic task; however, even initializing randomly achieves 54.5% for 13-class scale 1 only, still the largest contribution, albeit by a smaller amount).

7.2. Effect of Depth and Normals Inputs

The fact that we can recover much of the depth and normals information from the RGB image naturally leads to two questions: (i) How important are the depth and normals inputs relative to RGB in the semantic labeling task? (ii) What might happen if we were to replace the true depth and normals inputs with the predictions made by our network?

To study this, we trained and tested our network using either Scale 2 alone or both Scales 1 and 2 for the 13-class semantic labeling task under three input conditions: (a) the RGB image only, (b) the RGB image along with predicted depth and normals, or (c) RGB plus true depth and normals. Results are in Table 7. Using ground truth depth/normals shows substantial improvements over RGB alone. Predicted depth/normals appear to have little effect when using both scales, but a tangible improvement when using only Scale 2. We believe this is because any relevant information provided by predicted depths/normals for labeling can also be extracted from the input; thus the labeling network can learn this same information itself, just from the label targets. However, this supposes that the network structure is capable of learning these relations: If this is not the case, e.g. when using only Scale 2, we do see improvement. This is also consistent with Section 7.1, where we found the coarse network was important for prediction in all tasks — indeed, supplying the predicted depth/normals to scale 2 is able to recover much of the performance obtained by the RGB-only scales 1+2 model.

8. Discussion

Together, depth, surface normals and semantic labels provide a rich account of a scene. We have proposed a simple and fast multiscale architecture using convolutional networks that gives excellent performance on all three modalities. The models beat existing methods on the vast majority of benchmarks we explored. This is impressive given that many of these methods are specific to a single modality and often slower and more complex algorithms than ours. As such, our model provides a convenient new baseline for the three tasks. To this end, code and trained models can be found at [http://cs.nyu.edu/~deigen/dnl/](http://cs.nyu.edu/~deigen/dnl/).
