ABSTRACT

The Large Binocular Telescope Interferometer (LBTI) can perform Fizeau interferometry in the focal plane, which accesses spatial information out to the LBT’s full 22.7-m edge-to-edge baseline. This mode has previously been used to obtain science data, but has been limited to observations where the optical path difference (OPD) between the two beams is not controlled, resulting in unstable fringes on the science detectors. To maximize the science return, we are endeavoring to stabilize the OPD and tip-tilt variations and make the LBTI Fizeau mode optimized and routine. Here we outline the optical configuration of LBTI’s Fizeau mode and our strategy for commissioning this observing mode.

Keywords: Large Binocular Telescope, LBTI, interferometry

1. INTRODUCTION

The facility which was later to become the LBT had interferometry directly in its strategic sights since the facility’s earliest conceptual designs in the 1980s [1]. It was recognized that a large, > 10 m class telescope optimized for the infrared would unlock a host of science cases, but that manufacturing and handling limitations precluded the construction of a giant, continuous mirror.

Consequently, and based on experience with the co-phased Multiple Mirror Telescope (MMT), the LBT aperture was ultimately split into two 8.4 m mirrors separated by 6 m [2, 3]. The inner separation of 6 m between the two primary mirrors was “a compromise between maximum angular resolution (i.e., maximum baseline) and continuity of spatial frequency response” [2]. In other words, the shortest baselines which stretch from one mirror to the other are degenerate with the longest baselines achievable within a single mirror, which allows continuity in the LBT aperture’s sampling of frequency space of observed targets (Table 3).

Today, the LBT’s discontinuous aperture has the longest baseline of any other astronomical telescope on a single mount. The LBT is the only infrared-optimized telescope in the world with an achievable resolution on the scale of future extremely large telescopes (ELTs), and it will be in a unique position to corner ELT science cases until the first ELTs are operational in the mid-2020s. Indeed, those first ELTs (the GMT and E-ELT) will be southern facilities, and the northern TMT is projected to come online in the late 2020s.

Since atmospheric aberrations destroy angular information content over large baselines, infrared imaging interferometry requires a high-end adaptive optics system. As of spring 2018, the LBT/LBTI adaptive optics (AO) system samples the wavefront deformation over a grid of up to 30×30 over the aperture, and sends compensating signals at up to ~1 kHz to a deformable secondary mirror. The use of the secondary mirror as the deformable mirror acts to improve throughput and remove infrared background emission [4].

The LBT Interferometer (LBTI) instrument sits between the primary mirrors and can access the LBT’s dual-aperture baselines through interferometric synthesis. After the light from the primary mirrors hits the deformable secondary mirrors, tertiary mirrors guide the f/15 beams into the LBTI’s cryogenically-cooled Universal Beam
Figure 1: A heuristic representation of the uv coverage of an observation at 3.7 µm with 60 degrees of rotation. The curved, red solid lines indicate the uv coverage if the observation were obtained in a nailing (co-axial) configuration. This representation is inadequate in Fizeau (multi-axial) mode, where the uv coverage must be represented with a contour plot, here in linear scale. Note that the contours are not circularly symmetric because the speed of the on-sky parallactic angle rotation is not constant. (As in [2], we mask the low-frequency node to bring out detail in the higher frequencies.) The dashed line indicates the outer limit of obtainable frequency information, as imposed by the edge-to-edge baseline of the two primary mirrors.

Combiner (UBC) [5]. The UBC guides the beams within a f/15-envelope to a common focus, after which the light is sent to either of two science channels: LMIRCam [6, 7] (1-5 µm) and/or NOMIC [8] (currently 8-14 µm). A third channel, PhaseCam [9], is a fringe-tracking detector sensitive to H- and K_S-bands.

LBTI can observe in a number of high-contrast modes (see [10] in these proceedings). These include two main interferometric modes: 1.) nailing with NOMIC, in which the beams are combined in a plane close to a pupil plane (i.e., co-axial beam combination) and a π phase shift in one arm is used to place a destructive fringe over the central light source [11]; or 2.) imaging (also known as “Fizeau”) interferometry with LMIRCam and/or NOMIC, in which the beams are combined in a focal plane (i.e., multi-axial beam combination) and the sampled uv is more extended in frequency space, making available more spatial information at continuous frequencies for image reconstruction. (See Fig. 1.)

Nulling is advantageous for suppressing the bright light from host stars and for detecting faint, extended circumstellar material inside small fields-of-view. Since the pupils are overlapped, there is a one-to-one mapping of pairs of points between the two apertures at separations of 14.4 m. Thus nulling allows the extraction of angular resolutions equivalent to the 14.4 m center-to-center mirror separation. In Fizeau interferometry, the beam combination in the focal plane allows extraction of detail out to the 22.7 m edge-to-edge separation of the two mirrors.¹ This represents by far the largest optical or infrared Fizeau baseline in the world.

Until now, the great majority of LBTI interferometric observations have been in nailing mode as part of the Hunt for Observable Signatures of Terrestrial Systems (HOSTS) survey of exozodiacal dust around nearby (< 30 pc) stars [12, 13, 14]. This survey has been funded since 2001 by NASA’s Exoplanet Exploration Program

¹This includes the stopping-down of the LBTI pupils by the undersized secondary mirrors.
Figure 2: A pencil-beam schematic of the Universal Beam Combiner (UBC), upstream of the NIC cryostat, as of spring 2018. This shows elements and sources of pathlength and tip-tilt the beams encounter, as in Fig. 3. Some liberty has been taken with the fold angles for clarity. (For more physical angles, see, for example, [5].) Grey arrows (or arrowhead points and tails) show possible directions of movement of the wavefront sensors, and “flowerboxes” which hold a calibration laser source.

(ExEP) in order to constrain the noise contribution of exozodiacal dust so as to inform designs of future space-based exoplanet direct imaging missions, particularly with regard to primary mirror sizes [15, 16]. HOSTS science observations began in the spring 2014 observing season and came to a successful end in spring 2018, setting the stage for a segue to commissioning of the Fizeau interferometric mode.

Our main goal in this article is to outline how we will implement a “controlled” Fizeau mode, whereby the single-aperture PSFs are kept overlapped and the fringes are actively kept stable, and at the center of the coherence envelope. Stable fringes will avoid phase smearing and will increase observing efficiency by making a larger proportion of detector readouts useable and by allowing longer integrations.

The technical potential for commissioning routine imaging interferometry in the infrared is scientifically timely. High-contrast, AO-corrected imaging interferometry with the LBT can unlock a host of cutting-edge science involving thermally-emissive structure at tiny angular scales, including the detailed imaging of protoplanetary and transition disks, binarity searches in crowded fields, and the probing of the distribution of material in the inner regions of exoplanetary systems. Among other targets, the Taurus-Auriga region of natal circumstellar disks, at 140 pc away, is clearly one of the most interesting. Other emerging facilities like ALMA will provide complementary data on natal exoplanetary systems (e.g., [17]). With nulling in a highly commissioned state, controlled Fizeau is the next step in expanding LBTI’s interferometric capabilities.

Figure 3: A schematic of the Nulling Infrared Camera (NIC) cryostat, which is downstream of the Universal Beam Combiner (UBC), as of spring 2018. This schematic is drawn to indicate all optical elements the beams encounter. All instrumental sources of alterable tip, tilt, and OPD are indicated, in parentheses under the relevant element: "TT" is tip/tilt; "piston" is micron-scale piezo piston (and hence OPD) variations; "translation" is millimeter-scale OPD by moving the element on a translation stage. (See Table 1.) Elements in pupil planes are indicated with purple color and the ‘PP’ symbol, and elements in focal planes with green color and ‘FP’. Each dotted box represents a physical level of the cryostat. Note that in closed Phasecam loop, the Phasecam detector image is actually closest to a pupil plane because of the Demag Lens Wheel. The science detectors can also image pupil planes with an appropriate lens in LMRCam’s filter wheel 4, or NOMIC’s filter wheel 1.)
2. THE STATE OF FIZEAU SCIENCE WITH LBTI

2.1 Prior work

The LBT obtained its first seeing-limited Fizeau fringes in October 2010 in N-band, using the former MMT telescope instrument MIRAC4-BLINC while it was hooked up to the LBTI external structure for preparatory tests [18, 19]. The LBT right and left adaptive secondary mirrors were installed in 2010 and 2011, and have been doing regular science since 2011 and 2012, respectively [20, 21, 22]. LBTI (with the current NIC cryostat [18]) obtained the first AO-corrected (but not phase-controlled) Fizeau images with LMRCam and NOMIC in April and May 2012 [21]. Finally, K$_S$-band phase-tracking with Phasecam was coupled to the nulling mode beginning in December 2013 [23].

An LBT Fizeau PSF would ideally look very much like the simulated image in the top row of Table 3, or more physically like that in Fig. 4b. The familiar bright and dark Airy rings of a diffraction-limited PSF from a single, circular aperture of 8.25 m (undersized from 8.4 m by the secondary mirror) is multiplied by a linear sinusoid from the offset between the two apertures. For a finite bandwidth, high-contrast fringes are only seen near an optical path difference (OPD) of zero between the two beams. The LBT’s AO system routinely corrects the wavefronts in the beams to Strehls of $\gtrsim 85\%$ at 4 $\mu$m [24], but the two adaptive secondaries apply independent corrections which are blind to differential piston. There can still be strongly time-varying, atmospherically-induced differential piston (on the order of 10 $\mu$m on a timescale of a few minutes [25]) or other aberrations between the two corrected wavefronts.

Fringe phase in the PSF depends on the OPD between the two beams, and differential piston manifests itself in the LBT PSF as a rolling of the fringes through the Airy rings (Table 3, row 4). If the OPD veers further away from the center of the fringe packet, the visibility of the fringes decreases. At large enough OPD, the beams are essentially incoherent, and the illumination on the detector becomes that of a single Airy function with twice the amplitude of a single aperture (Table 3, row 5). To avoid fringe smearing and remain in the center of the coherence envelope, the path difference between the beams must be actively controlled.

Some early scientific work has been done in “lucky” Fizeau mode, involving detailed M-band imaging of the volcanically active Jovian moon Io [26, 27, 28, 29]. A small handful of other targets have been Fizeau-imaged for testing purposes, including Vega [8], HD 184786 [25], CH Cyg, and a collection of stars in the Trapezium asterism, separated by several arcseconds to demonstrate wide-field co-phasing [30]. However, without active phase control, time-varying differential OPD and tip-tilt instability remain, and cause fringes to jitter back-and-forth in the focal plane. Furthermore, short integration times are necessary to avoid phase smearing [19, 31]. In the reduction phase, the “lucky” frames with centered fringes are sieved from the rest. In terms of the useful detector integration time compared to total integration time, the efficiency until now has been extremely low. Stated efficiencies in the literature range from 2-5 % [27], ~5-10% [26], and ~10-20% [28]. These percentages do not include time that is lost 1.) during the readout of the necessarily short exposures to avoid fringe smearing (e.g., [26, 27]), and 2.) due to the manual nature of the observation, such as when members of the observing team have to manually tune a correction mirror at each telescope dither position, to find the center of the coherence envelope as best as possible.¶

Since a bright fringe passes through the PSF center for every wavelength of OPD, the fringes in the “lucky” frames are of unknown distance in OPD from the center of the coherence envelope, where the visibility is best. The fringes in “lucky” frames are from somewhere near the center of the coherence envelope, but it is unknown how near. A simple measurement of fringe positions from one image to the next only yields OPD modulo $\lambda$, rather than a true OPD (as measured from the center of the coherence envelope, or in the differential OPD...§

¶We should note that strictly speaking, the PSF is the target-independent instrument impulse response, which must be convolved with a perfect, instrument-independent image of the object $O$ to yield the image $I$ on the detector, or $I = PSF * O$. For simplicity, however, we use “PSF” loosely in this article to refer to the irradiance on the detector, because we only consider point source targets (i.e., delta functions). Naturally, our ultimate hope is to conduct Fizeau observations of objects considerably more interesting than delta functions.

§Note that a bright resolved source like Io cannot be phase-controlled with Phasecam, because the extended nature of the source means that the interferometric visibility will be too low. Nevertheless, these low observing efficiencies illustrate what one would get by observing a point source without active phase control.
Table 1: Controllable sources of OPD, Tip, Tilt

| Element                     | Plane | Upstream of all detectors? | Degree of freedom / range on sky at cryogenic temperatures | Remarks / advantage               |
|-----------------------------|-------|-----------------------------|-----------------------------------------------------------|-----------------------------------|
| NIL beam combiner           | ≈Pupil | N                           | OPD: 24 mm                                                | Co-alignment of coherence envelopes during setup |
| Fast pathlength corrector (FPC) | Pupil | Y                           | OPD: 2 × 50 µm (piezo) = 100 µm Tip/tilt: ≈±5 asecs      | Automated removal of differential piston, 1 kHz (Phasecam loop) |
| Hybrid pathlength corrector (HPC) | Pupil | Y                           | OPD: 2 × 16 mm (transl. stage) +2 × 50 µm (piezo) ≈ 32.1 mm Tip/tilt: ≈±5 asecs | Manual scanning for coherence envelope during setup |
| Pupil steering mirror (PSM) | –     | N                           | OPD: 2 × 20 µm = 40 µm Tip/tilt: ≈±0.4 asecs             | Semi-static                       |
| Field steering mirror (FSM) | ≈Pupil | N                           | OPD: 2 × 20 µm = 40 µm Tip/tilt: ≈±0.4 asecs             | Semi-static; iterative movement of PSM and FSM allows translation of Phasecam pupils |

from one frame to the next). There is a lot of room to move—depending on the transmission filter profile, there could be ten or so bright fringes in the coherence envelope (e.g., Fig. 2). If the frames with centered fringes are co-added for higher signal-to-noise, the obtainable contrast is washed out through the mixture of different phases.

2.2 The current technical problem

Design of any strategy for controlling and optimizing the Fizeau imaging mode requires an understanding of the two beam paths. After reflecting off the primary mirrors, the atmospherically-aberrated wavefronts are, to a high approximation, flattened out by the deformable secondary mirrors. The light then reflects off the static telescope tertiary mirrors and towards the telescope bent Gregorian foci at the LBTI Universal Beam Combiner (UBC). A dichroic sends the visible light into the wavefront sensors while allowing the infrared light to proceed into the cryogenic UBC (Fig. 2) and on into the Nulling Infrared Camera (NIC) cryostat which contains the detectors (Fig. 3).

In nulling mode, the Phasecam (phase-tracking) and NOMIC (science) channels are common until they reach a nulling dichroic which sends the H- and Ks-band light to Phasecam and the N-band light to NOMIC. The detectors are both downstream of all (intentionally) adjustable sources of OPD, tip, and tilt. (See Table 1.)

In contrast, both the LMIReCam-Fizeau and NOMIC-Fizeau channels are highly non-common from that of Phasecam (Fig. 3). The LMIReCam and Phasecam channels split at a beam diverter which sits right inside the entrance of the NIC cryostat. The NOMIC-Fizeau channel splits from Phasecam two optical elements further downstream. The LMIReCam and NOMIC-Fizeau channels are blind to OPD and tip-tilt variations induced by the NIL steering mirrors and beam combiner (Table 2). To make a Fizeau PSF with LMIReCam or NOMIC, the beams must be combined on the plane of the detector itself.

This leads to the following issues: the science and phase-sensing channels are more prone to differential OPD or tip-tilt, and the science and phase-sensing channels require separate beam combination. Delicate alignment is required to achieve co-alignment of the coherence envelopes to image the zero-OPD interferometric PSFs on both detectors, and this alignment must be maintained for the duration of the observation.

The center of the coherence envelope can be sought manually by dispersing the PSF with a grism and moving a pathlength corrector mirror (HPC) with a piezo and translation stage back and forth until obtaining “barber

footnote: LBTI does not currently have the optics to enable LMIReCam to observe in nulling mode, so we will henceforth label the LMIReCam-Fizeau channel as simply ‘LMIReCam’.

Figure 4: a.) Strip-like images are, from left to right: “barber-pole” fringes as produced by a 2.8-4.2 μm L-band grism [32], during the initial search for the coherence envelope on LMIRcam; a fast Fourier transform of the “barber-pole” fringe image, with logarithmic color scaling; an image of the fringes when they are roughly vertical after minimizing the OPD with the use of the HPC pathlength corrector mirror; and its fast Fourier transform. b.) A physical L′-band Fizeau PSF, complete with lumpy optical “ghosts”, captured in May 2018. The greyscale is nonlinear to show the structure in the outer Airy rings. Bright Airy rings are visible out to several λ/D, where $D = 8.25$ m is the effective diameter of one primary mirror.

pole” fringes (which derive their shape from the wavelength-dependent phase difference). The OPD must be changed until the fringes are straightened, so as to indicate a common OPD in units of wavelength across the entire bandpass (i.e., the OPD must be zero). In the process, an algorithm may make use of fast Fourier transforms of the barber-pole images so as to sense and minimize the slant of the fringes (Fig. 4a).

As a first step in controlling the PSF, Phasecam needs to be coupled to the Fizeau mode to provide a first-order correction to OPD variations. In closed loop, Phasecam sends compensating signals to the fast pathlength corrector (FPC) mirror to remove effects of instrument flexure (<< Hz) and the atmosphere (~10 Hz). In order to maintain the image on Phasecam, pathlength and tip-tilt setpoints set the zero levels around which the FPC can move in piston, tip and tilt. Phasecam has limitations, however. It can only partially remove the 5-10 μm contributions of telescope resonances at 12-18 Hz and instrument (particularly UBC) vibrations at 100-150 Hz. In addition, Phasecam experiences occasional “phase jumps” due to the strong 2π phase degeneracy between fringes (see Table 2 and [33] in these proceedings). Until now, those jumps have had to be counteracted manually in real-time, resulting in some loss in efficiency. Thus Phasecam provides an important but incomplete source of control over the PSF.

To adapt Phasecam for Fizeau, additional controls are needed which will carry out the following: 1.) Telescope movements to make and maintain PSF overlap in the focal plane; 2.) Seeking and maintaining the center of the coherence envelope of the science bandpass; 3.) Calculation of OPD and tip-tilt setpoints which form the basis for the Phasecam loop which applies realtime corrective movements of mirrors for phase control; and 4.) Repeat the above steps after every telescope nod, dither, or opening of the Phasecam loop, to counteract mechanical hysteresis and optical realignments.

To be clear, at the highest level there are three control loops acting in parallel for Fizeau (or nulling) observations:

1. Left telescope AO control loop: wavefront correction based on secondary mirror deformation
2. Right telescope AO control loop: (the same)
3. Phasecam phase control loop: OPD and tip-tilt correction via the fast pathlength corrector mirror
A Fizeau calibration loop will supplement these by providing gross PSF alignment, followed by repeated coherence envelope alignment and calculation and setting of OPD and tip-tilt setpoints.

The first control loop listed above will be upgraded in the summer of 2018 as part of the SOUL project [34]. The second will be upgraded later on. Work is progressing to upgrade the third to supplement the \( R_S \)-band correction with \( H \)-band (see [33] in these proceedings). The Fizeau calibration loop does not yet exist, and the general methodology is explained in the following section. (The methodology for finding equivalent setpoints in nulling mode are described in [35].)

### 2.3 Envisioned Fizeau calibration loop

The detector science readouts themselves will provide the best real-time data on OPD or tip-tilt variations that have escaped correction by Phasecam. The initialization of observations will just be an automated version of what is currently done manually: a Fizeau calibration loop should begin by moving both telescope images close together, putting in a grism, and adjusting OPD with a corrector mirror (the slow pathlength corrector in the UBC) until barber pole fringes are acquired and straightened. Once at the center of the coherence envelope, the grism is removed. The NIL beam combiner, which is upstream of Phasecam but not the LMIRcam or NOMIC Fizeau channels, is then translated to find the center of the coherence envelope on Phasecam.** Two static tuning surfaces, the Pupil and Field Steering Mirrors, can provide tip-tilt (and also OPD, if necessary) to the Phasecam pupils to optimize the fringes for tracking.

To convert information encoded in the science detector image into a form that is rapidly interpretable, we will Fourier transform the illumination on the detector. (An initial exploration of this idea was made in [36].) For a perfect point source, this is essentially the same as Fourier transforming the PSF into the complex optical transfer function (OTF):

\[
FT \{ PSF(x, y) \} \equiv OTF(\zeta, \eta) \equiv MTF(\zeta, \eta)e^{-iPTF(\zeta, \eta)}
\]

where \((x, y)\) are coordinates in the detector plane and \((\zeta, \eta)\) are in the Fourier plane. The modulation transfer function (MTF) is the modulus of the Fourier transform, and represents the amount of retrievable contrast of the object \(O\) as a function of spatial frequency (e.g., [37]). The phase transfer function (PTF) is the phase of the Fourier transform, and is particularly sensitive to asymmetries in the PSF. The MTF and PTF will be used to diagnose nonzero OPD, tip, tilt, and possibly other aberrations. The Fizeau calibration loop will calculate the necessary corrections and send signals to movable elements, be they mirrors or the NIL beam combiner (Table 1).

We have made custom simulations of the LMIRcam PSF with different perturbations to tease out diagnostic quantities. Table 3 shows simulated PSFs along with their MTFs and PTFs. Some things are of note in the unambiguated Fizeau PSF in the top row. The MTF has three lobes: a central one representing the low-frequency structure of the single-mirror Airy function, and the symmetric high-frequency sidelobes which encode the narrow fringing from the separation of the two primary mirrors. The MTF lobes overlap due to the degeneracy between some baselines that can fit within a single mirror, and those across both mirrors. Indeed, the span between the mirrors was chosen to allow this continuous sampling in the first place (see Sec. 1). The PTF is just a flat plane where the OTF is nonzero, because the PSF is symmetric.

When the center of the coherence envelope is on either LMIRcam or NOMIC, the illumination on the other science detector should also be close to zero OPD, because both the LMIRcam and NOMIC optical trains were built to have the same focus at the detector. There may, however, be some residual defocus between them. There are currently no optics for changing the OPD between LMIRcam and NOMIC, so if Fizeau on both detectors is desired, then a Fizeau calibration loop using the readouts of only one detector could have the option of choosing the detector of the highest science priority and allow the other detector to piggyback, or choose the detector with the shortest integration times (for faster correction) or greatest Fizeau calibration loop stability (for continuous correction) and impose an OPD offset to accommodate the other detector.

**It is possible to offload OPD corrections from the FPC to the NIL beam combiner, but this is inadvisable in Fizeau mode because it would separate the coherence envelopes.
Figure 5: A boolean plot showing when Fizeau science frames were taken with the Phasecam loop closed or open during a science observation in May 2018. Phasecam stayed closed continuously for ~few minutes at a time.

Table 2: Qualitative comparison of physical, on-sky PSFs when Phasecam is in open or closed loop

|     | Open loop | Closed loop |
|-----|-----------|-------------|
|     |           |             |
|     |           |             |
|     |           |             |
|     |           |             |
|     |           |             |
| t = 0.00 sec | t = 0.90 sec | t = 1.81 sec | t = 2.71 sec | t = 3.61 sec | t = 4.51 sec |

Physical PSFs obtained on-sky in May 2018, during the first sustained phase-controlled Fizeau observations with LBTI. Note the phase jump between $t = 2.71$ sec and $t = 3.61$ sec in the bottom row.

2.4 First on-sky phase-controlled Fizeau science observation

In May 2018, Phasecam successfully phase-tracked a Fizeau observation of a bright star for up to a few minutes at a time, over a total range of two hours (Fig. 5). This was in seeing conditions that sometimes skirted the edge of the permissible range (Fig. 7). Fig. 4b shows an example PSF from that observation, and Table 2 compares the PSF from that observation with and without Phasecam phase tracking over a period of a few seconds. The uncontrolled PSF exhibits OPD instability as well as phase smearing which has a detrimental effect on visibilities. The phase-controlled PSF is much more stable, though it occasionally suffers phase jumps equivalent to one wavelength in $K_S$-band.

This observation was an important proof-of-principle that Fizeau with at least partial phase control can indeed be conducted for sustained periods with LBTI. In the process, the observing team gained a clearer picture of the technical exigencies of a more controlled Fizeau mode, including the updating of correction mirror setpoints, optimization of the Phasecam pupil illumination, counteraction of mirror hysteresis, and dealing with assorted complications such as the jumping away of the left-aperture component of the PSF in the focal plane when the Phasecam loop breaks. Reduction of the science dataset is ongoing.
Table 3: Simulated Fizeau image diagnostics

|                  | PSF | MTF | PTF | Potential diagnostic                                |
|------------------|-----|-----|-----|-----------------------------------------------------|
| ‘Perfect’ Fizeau | ![PSF image](image) | ![MTF plot](image) | ![PTF plot](image) | -                                                   |
| Diff. tip (±y), 0.03" | ![PSF image](image) | ![MTF plot](image) | ![PTF plot](image) | Global, continuous phase gradient in y across all nodes |
| Diff. tilt (±x), 0.03" | ![PSF image](image) | ![MTF plot](image) | ![PTF plot](image) | Phase gradient in x across individual nodes          |
| Small OPD, 0.5 µm | ![PSF image](image) | ![MTF plot](image) | ![PTF plot](image) | Global phase gradient, but with flat phase value in each node |
| Large OPD, 50 µm | ![PSF image](image) | ![MTF plot](image) | ![PTF plot](image) | Low power in high-freq nodes of MTF; PSF approximates incoherent overlapping of two single-aperture images |
| Transl. in x, 0.5 pix | ![PSF image](image) | ![MTF plot](image) | ![PTF plot](image) | Compression of nodes in x, along with global phase gradient in x |
| Transl. in y, 2.0 pix | ![PSF image](image) | ![MTF plot](image) | ![PTF plot](image) | Compression of nodes in y, along with global phase gradient in y |

PSF images are simulated with the LMIRcam sampling, i.e., 0.0107”/pixel. The blue lines in the 1D plots are horizontal and vertical cuts through the images. The 1D plots for the PSF images are normalized to the maximum of a ‘perfect’ Fizeau PSF, whereas in the 1D plots for the MTFs, each plot is normalized with itself. Note the MTFs never go to zero between the nodes. The PTF 1D plot ranges are fixed to ±180°. Note some artifact aliasing appears in some images.
Figure 6: A cartoon comparison of Fizeau-mode coherence envelopes on the science detectors and Phasecam at different stages of the OPD alignment. The modulation envelope due to the finite width of the filter bandpass is indicated with dashed lines. (Note that the NOMIC envelope here is only in NOMIC-Fizeau mode. In nulling mode, the Phascam and NOMIC fringe envelopes share identical pathlengths by design.) After AO loop closure but before any mirror alignment. The coherence envelopes are at unknown OPD from the detector planes. b.) After inserting the grism, adjusting a pathlength corrector mirror, and acquiring and aligning the barber-pole fringes on either of the science detectors (see Fig. 4a). This action also changes the OPD on Phasecam. c.) After adjusting the NIL beam combiner to center the coherence envelope on Phasecam. The NIL beam combiner is upstream of Phasecam and NOMIC-nulling, but not LMIRcam or NOMIC-Fizeau, so this will not change the OPD on the science detectors in Fizeau mode. The grey bar has width 5 µm to show the possible range of tolerance of the Phasecam loop before it opens.

Table 4: Current observing target requirements for performing controlled Fizeau

| Parameter          | Requirement                        | Remarks                                                                 |
|--------------------|------------------------------------|-------------------------------------------------------------------------|
| DEC                | ≥ 5°                               | Constrained by LBT latitude and the need for ≤1.2” seeing (see Fig. 7)  |
| Visibility         | ≥60-80% in K₉-band                 | Phasecam cannot lock onto extended sources.                             |
| Observing wavelength| L-, M-, or N-bands (limited sensitivity in K-band) | Limited K-band is possible by reflecting some of this into Phasecam and some of it towards LMIRcam. |
| R-band brightness  | m₉ ≤ 9 mag (300 modes, 990 Hz)     | For AO correction. Note AO guide stars have been acquired as far as ~30” off-axis from the science target, but bright Fizeau targets will likely not require off-axis guide stars |
| of AO guide star   | 9 ≤ m₉ ≤ 10.5 (153 modes, 990 Hz)  |                                                                         |
|                    | 10.5 ≤ m₉ ≤ 12.5 (66 modes, 990 Hz) |                                                                         |
|                    | 12.5 ≤ m₉ ≤ 14.5 (66 modes, 100s Hz) |                                                                         |
|                    | 14.5 ≤ m₉ ≤ 17.5 (36 modes, ∼100 Hz) |                                                                         |
| K-band brightness  | m₉ ≤ 4.7 for correction as slow as 520 Hz | For fringe tracking with Phasecam at standard detector binning. Slower cadences and adjustments in summer 2018 may allow phase control of dimmer targets. (In principle it is possible to slow down the integration cadence until it dips below the atmospheric coherence timescale, at which point phase tracking becomes impossible. Fringe tracking can be neglected entirely at a steep cost in observing efficiency (see Sec. 2.1).) |
Figure 7: Contoured region shows first-order limits on pointing in Fizeau mode, as imposed by line-of-sight seeing. Line-of-sight and zenith seeing are interconverted by a factor of $\sin(EL)$. (Note that variations in EL tolerances and the validity of the $\sin(EL)$ conversion can occur due to airflow and localized turbulence around the dome.) Favorable EL values of targets are within the contoured area. EL below 45 degrees is greyed out because the Phasencam loop becomes difficult to close below this threshold. The AO cannot perform at all below 30 degrees. The orange and blue points are from data during a Fizeau observation in May 2018 (see Sec. 2.4). “Phase control” is when Phasencam was actively controlling fringes. Note that some of the non-phase-controlled points were from during setup or alignment.

3. THE FUTURE

During spring 2018 observations, we applied Phasencam phase control to the high-contrast Fizeau mode for the first time for any appreciable duration. This also gave the observing team experience for stabilizing the Fizeau mode in the future. Some of the current prerequisites for observing in Fizeau mode are summarized in Table 4, and in the future these prerequisites may be loosened.

During the summer of 2018, we will work to construct a Fizeau calibration loop which uses science detector readouts to provide control that supplements the action of Phasencam. We have accordingly applied for time in fall 2018 to do on-sky testing. In the meantime, an upgrade of the left-side wavefront sensor was made in summer of 2018 as part of the SOUL project [34], after which the wavefront sensor is able to supply finer samplings, from $30 \times 30$ across the pupil to a grid of $40 \times 40$, and with a faster time response. Once both sides are upgraded, this will substantially improve the AO correction in mediocre weather conditions, meaning that there will be more opportunity for conducting imaging interferometry. We also hope to decrease the incidence of Phasencam’s phase jumps by supplementing the $K_S$-band pupils with $H$-band. (See [33] in these proceedings.) Reduction of already-captured Fizeau datasets will allow us to investigate achievable contrasts [38, 39] and make further improvements for making this observing mode routine.
