Abstract: We perform an analysis of the properties of radio-loud (RL) and radio-quiet (RQ) quasars with MgII broad emission line (i-band magnitude \( \leq 19.1 \) and \( z \leq 1.9 \)), selected from the parent sample of SDSS DR7 catalogue. For sources with full-width half maxima (FWHM) greater than 15,000 km s\(^{-1}\) (very broad line sample; VBL) we find the radio loud fraction (RLF) to be about 40%. To further investigate this result we compare the bolometric luminosity, optical continuum luminosity, black hole (BH) mass and Eddington ratios of our VBL sample of RL and RQ quasars. Our analysis shows that in our VBL sample space, RL quasars have higher luminosities and BH mass than RQ quasars. The similarity in the distribution of their covering fraction (CF) shows that there is no difference in dust distribution between VBL RL and RQ quasars and hence dust is not affecting our results. We also find that there is no correlation of RL quasar properties with optical continuum luminosity and BH mass.  

Keywords: radio-loud quasars; radio-quiet quasars; very broad line; bolometric luminosity; optical continuum luminosity; black hole mass; Eddington ratio; radio luminosity; covering fraction; radio-loudness  

Key Contribution: It is known in the literature that roughly 10% of the total quasar population is radio-loud (RL). In this study we show that for broad MgII emission line quasars, we do observe an increase in RL fraction with full width half maximum (FWHM). For FWHM greater than 15,000 km s\(^{-1}\), the radio loud fraction is greater than 40%.  

1. Introduction  

It has been widely reported in the literature that only a small fraction of the quasar population exhibits powerful radio emission in the form of radio jets e.g., (Sandage 1965; Strittmatter et al. 1980; Schmidt & Green 1983; Kellermann et al. 1989; Miller et al. 1993; Ivezić et al. 2002; Jiang et al. 2007; Rafter et al. 2011), despite its very first detection in the radio band (Schmidt 1963). The radio-to-optical flux density ratio for optically selected quasars, appears to be bimodal, suggesting that there could be two distinct populations of objects, namely radio-loud (RL) and radio-quiet (RQ) quasars (Strittmatter et al. 1980; Kellermann et al. 1989; Miller et al. 1990; Ivezić et al. 2002; White et al. 2007; Zamfir et al. 2008). The search for bimodality has spanned different parameter spaces of quasar properties, namely, black hole (BH) mass (McLure & Jarvis 2004), origin of radio emission (Laor & Behar 2008), accretion rates (Sikora et al. 2007; Hamilton 2010), host galaxy properties (Sikora et al. 2007; Lagos et al. 2009; Kimball et al. 2011), and BH spins (Blandford & Znajek 1977; Blandford 1990; Garofalo et al. 2010). Some recent studies suggest that black holes might be systematically heavier in
RL sources than those in RQs (Dunlop et al. 2003; Chiaberge et al. 2005; Jarvis & McLure 2006; Magorrian et al. 1998; McLure & Dunlop 2001; Laor 2000).

The formation and launching of radio jets is not well understood, but the Blandford-Znajek (BZ) mechanism (Blandford & Znajek 1977) remains as the most plausible theoretical explanation. It has been observed in many studies, that a correlation exists between emission line luminosities originated from the disk, and radio luminosities of jets in RL quasars (Osterbrock 1977; Baum & Heckman 1989; Saunders et al. 1989; Rawlings & Saunders 1991; Zirbel & Baum 1995; Willott et al. 1999; Buttiglione et al. 2010; Sikora et al. 2013). It has been further reported that there exists some correlation between the radio luminosity and BH mass in RL quasars (Franceschini et al. 1998; Laor 2000; Lacy et al. 2001; McLure & Jarvis 2004) but the claim has been debated by other groups (Oshlack et al. 2002; Woo & Urry 2002; Ho 2002; Snellen et al. 2003).

In this work, we have identified a sample of RL and RQ quasars with broad MgII emission lines from the parent catalog of Shen et al. (2011). Our analysis shows that the radio loud fraction (RLF) increases with full width half maximum (FWHM) for our sample Chakraborty & Bhattacharjee (2021a). To further investigate this feature we construct a subsample (Very Broad Sample; VBL hereafter, FWHM > 15,000 km s⁻¹) from the broad MgII sample and perform a thorough comparison of the different properties of RL and RQ quasars.

2. Materials and Methods

We now provide a brief description of the datasets and the analysis methods that we utilized in this work. Our parent sample came from the Sloan Digital Sky Survey SDSS (York et al. 2000) Data Release 7 (Abazajian et al. 2009) quasar catalog (Shen et al. 2011). It consisted of 105,783 spectroscopically confirmed quasars brighter than Mi = −22.0. Shen et al. (2011) cross matched the quasar catalog of SDSS DR7 with the Faint Images of the Radio Sky at Twenty-cm (FIRST) survey. The quasars having only one FIRST source within 5″ were classified as core-dominated radio sources and those having multiple FIRST sources within 30″ were classified as lobe dominated. These two categories were together compiled as RL quasars by Shen et al. (2011). Quasars with only one FIRST counterpart between 5″ and 30″ were classified as RQ quasars. We checked optical spectra of the VBL quasars from SDSS, and the quasars which had inconsistencies in their broad MgII lines were manually discarded from our sample. Among SDSS quasars, the total number of quasars that had confirmed FIRST counterparts was 99,182. Among these quasars, 9399 were RL quasars and 88,979 were RQ quasars. We applied a redshift cut of z ≤ 1.9 for our MgII sample which restricted our sample size. Moreover, to avoid biasing in the radio properties, we further applied a cut in the i band magnitude (i < 19.1). Our final MgII VBL sample consisted of 14 RL and 22 RQ quasars.

3. Results

In Chakraborty & Bhattacharjee (2021a), we studied the distributions of bolometric luminosity, optical continuum luminosity at 3000 Å and virial BH masses of RL and RQ quasars in our VBL sample and found them to be slightly different from the parent sample of Shen et al. (2011). We have found in Chakraborty & Bhattacharjee (2021a) that our VBL RL quasars have marginally higher luminosities and BH masses compared to RQ quasars while in the parent sample there is no difference of the said properties between RL and RQ quasars. In this work we further investigated the properties of RL and RQ quasars of our VBL sample to search for clues regarding the increasing RLF with FWHM.

3.1. Studying Properties of the Very Broad Line Sample

In the left panel of Figure 1, we show the variation of optical continuum luminosity with BH mass for our VBL sample. From the figure we can clearly see RLs on average had higher
luminosity as well as higher BH mass. Additionally, we observed that the four most massive objects which were also the most luminous ones were RL (upper right corner). In the right panel, we show the same for Eddington ratios and covering fractions (CF). We computed the Eddington ratios using virial BH mass and bolometric luminosities. Both the bolometric luminosity and BH mass were taken from Shen et al. (2011) catalogue. We estimated CFs from the ratio of the integrated flux at mid-IR (MIR) to optical flux, which is the fraction of the optical flux emitted by the accretion disk that is absorbed and re-emitted into the IR by the dusty torus e.g., (Netzer 2019). From the figure we observe that there was no difference in the mean values of both Eddington ratios and CF between RL and RQ quasars for our VBL sample. It has been claimed in some studies that the torus is a smooth continuation of the broad line region BLR (Elitzur 2008). However, it is known that the torus causes anisotropic obscuration outside the BLR. CF is often used to quantify this obscuration. Hence, the similarity in the distribution of CFs reveals that our VBL sample was mostly unbiased from obscuration effect.

We performed a correlation analyses between bolometric luminosity, BH mass, and FWHM of our VBL RL and RQ quasars and Table 1 and Table 2 list the correlation coefficients. We observed in our sample that bolometric luminosity was not correlated with FWHM for both RL and RQ quasars however bolometric luminosity correlated with black hole mass for both RL and RQ quasars. Our analysis suggests that the correlation between bolometric luminosity and BH mass was stronger in RQ quasars compared to the RL ones. Lastly, we observed a modest correlation between BH mass and FWHM for our RL sample. We however wish to note that our results were based on small sample statistics, namely 14 RL and 22 RQ quasars.

**Figure 1.** (a) Left panel: Orange and blue solid circles denote the RQ and RL sources in our sample, respectively, on the optical continuum luminosity versus BH mass plane. (b) Right panel: the same on the Eddington ratio versus covering fraction plane. From the figure we note that the Eddington ratio and covering fractions of the RL and RQ quasars in our sample are similar.

3.2. Studies of Radio Luminosities

We found that optical continuum luminosity and BH mass were higher for RL quasars in our VBL sample. We now focus on the radio luminosities of our RL sample. The left panel of Figure 2 shows variation of $L_{rad}$ (radio luminosity at 6 cm) with $L_{3000}$, optical continuum luminosity at 3000Åand right panel showed the same with BH mass and $R$ (Zhang et al. 2021), where $R$ is radio loudness (ratio of radio luminosity and optical continuum luminosity) for our VBL RL quasars. We did not find any significant dependence of $L_{rad}$ on $L_{3000}$ and $R$ on the BH mass.
Table 1. Correlation Matrix for RL quasars of MgII VBL Sample.

|       | $L_{Bol}$ | BH mass | FWHM |
|-------|-----------|---------|------|
| $L_{Bol}$ | 1.0000 | 0.5922 | 0.2666 |
| BH mass   | 0.5922 | 1.0000 | 0.5766 |
| FWHM      | 0.2666 | 0.5766 | 1.0000 |

Table 2. Correlation Matrix for RQ quasars of MgII VBL Sample.

|       | $L_{Bol}$ | BH mass | FWHM |
|-------|-----------|---------|------|
| $L_{Bol}$ | 1.0000 | 0.8713 | -0.0095 |
| BH mass   | 0.8713 | 1.0000 | 0.1304 |
| FWHM      | -0.0095 | 0.1304 | 1.0000 |

4. Summary

In this study, we show that the radio loud fraction is increasing with FWHM for MgII broad emission line quasars at $z < 1.9$. To investigate the cause for the high RLF we construct the VBL sample (FWHM $> 15,000$ km s$^{-1}$) and perform an analysis to compare the properties of RL and RQ quasars. From the optical continuum luminosity distributions, we observe that for VBL, RLs have higher mean luminosities implying RLs to be intrinsically brighter than RQs. The difference in BH mass is similar to that of bolometric luminosity.

We checked for the correlation between bolometric luminosity, BH mass, and FWHM for our VBL sample. We have observed that bolometric luminosity and BH mass are strongly correlated and RQs have a higher correlation compared to RLs. However bolometric luminosity and FWHM are uncorrelated for both the populations. We do not observe any correlation between BH mass and FWHM for RQs while there is modest correlation for the RL population. In future we plan to further investigate to establish the significance of our results, for example we plan to fit the discarded SDSS optical spectra and include them in our analysis. We further note that we need to check for beaming effects in our sample which we propose to undertake with future observations. Our results do not reveal any strong difference between the properties of our VBL RL and RQ quasars but provide a hint toward a higher BH mass and higher bolometric luminosity of RL quasars compared to RQs. We note that, this might...
have some implications on the disc and jet connections in RL quasars and provide us clues with possible differences in the disc structures of RL and RQ quasars. In future, we propose to undertake further investigations using other emission line diagnostics as well as better methods of BH mass estimation in quasar systems.
