Abstract

We consider the interaction of two skyrmions in the framework of the sudden approximation. The widely used product ansatz is investigated. Its failure in reproducing an attractive central potential is associated with terms that violate G-parity. We discuss the construction of alternative ansätze and identify a plausible solution to the problem.

Keywords: Skyrme model, nucleon-nucleon interaction, chiral symmetry, effective Lagrangians.

1 Introduction

Nucleon-nucleon (NN) interactions are relatively simple at large distances and become rapidly more complex as one moves inward. In the best phenomenological models existing at present, that reproduce low-energy observables accurately, they are described by the consensual one-pion exchange potential (OPEP), supplemented by theoretical two-pion exchange potentials (TPEP) and parametrized at short distances [1, 2]. The OPEP is responsible for a strong tensor component, which is mostly important in few-body systems, such as the deuteron. Two-pion exchange, on the other hand, gives rise to the central potential, that survives to all averages and is responsible for most properties of large systems and nuclear matter. Quantum Chromodynamics (QCD) is the basic framework for the study of strong processes and should have, in principle, an important role in the description of nuclear forces. However, at present, the non-Abelian character of this theory prevents low energy calculations and one has to resort to effective theories, which must reflect the main features of QCD. Thus, in Nuclear Physics applications, besides the usual space-time invariances, one requires these theories to have approximate chiral symmetry. The latter is usually restricted to the $SU(2) \times SU(2)$ sector, for most processes involve only the quarks $u$ and $d$. This symmetry is explicitly broken by the small quark masses and, at the effective level, by the pion mass.

Chiral symmetry has no influence over the OPEP, but is crucial to the TPEP, which depends on an intermediate pion-nucleon (πN) amplitude \(^1\). In the case of \(NN\) interactions, the importance of this symmetry was stressed already in the early seventies, by Brown and Durso \(^3\) and by Chemtob, Durso and Riska \(^4\), who used it to constrain the form of the TPEP. In that decade it also became popular to describe nuclear processes by means of the linear σ model \(^5\), containing a fictitious particle called σ that, to some extent, simulates the TPE. The elimination of this unobserved degree of freedom gave rise to non-linear theories, which underlie modern descriptions of the interaction. The first theoretical framework to incorporate non-linear chiral dynamics into the \(NN\) problem was proposed by Skyrme. This remarkable model for the nucleon, developed in the sixties \(^6\) and revived in the eighties \(^7\), describes baryons as topological solitons, objects extended in space that rotate according to the laws of Quantum Mechanics. The quark condensate appears as an intrinsic feature, corresponding to a non-vanishing classical content of the vacuum, whose intensity is given by the pion decay constant \(f_\pi\). Skyrmions correspond to distortions of this condensate that carry topological charges. One then works with pion fields which are unusually strong, in the sense that their amplitudes may be comparable to \(f_\pi\). Thus, in spite of its well know limitations \(^8\), the Skyrme model remains a unique laboratory for studying chiral symmetry in the non-perturbative regime.

In the early nineties Weinberg restated the role of perturbative chiral symmetry in nuclear interactions \(^9\) and motivated interest in the TPEP. Initially, several authors explored the pion-nucleon sector of non-linear Lagrangians \(^10\), but the corresponding potentials could not reproduce even the medium range attraction in the scalar channel. This happened because the TPEP is based on an intermediate πN amplitude, that can only be well described with the help of other degrees of freedom \(^11\). Accordingly, in a later stage, agreement with empirical πN information was enforced and descriptions could reproduce \(NN\) scattering data \(^12, 13, 14\).

In the case of perturbative calculations, the delta is by far the most important non-nucleonic degree of freedom and is largely responsible for the intermediate range scalar attraction. As the Skyrme model incorporates the delta from the very beginning, one expects that it should yield a good qualitative \(NN\) potential. However, it fails to do so.

Skyrme himself considered \(NN\) interactions, already in the sixties, using the so called product ansatz (PA) \(^6\). The basic idea underlying the PA is that solutions corresponding to baryon number \(B = 1\) can be used as building blocks to construct approximate solutions with an arbitrary value of \(B\). The great advantage of this approach is that the baryon number of the composite system is automatically equal to the number of individual \(B = 1\) skyrmions, irrespectively of their relative positions. In the PA, the skyrmions that constitute a larger system are assumed to retain their shape all the time, what is known as sudden approximation. In this framework, the construction of the \(NN\) potential is rather simple and the fact that each nucleon has a profile function which falls off rapidly with the distance allows one to assume that, for medium and large distances, the \(B = 2\) system is not considerably different from the superposition of two with \(B = 1\).

In the eighties, the product ansatz was used by Jackson et al. \(^15\) and Vinh Mau et al. \(^16\) to calculate the \(NN\) potential, who found out a fully repulsive central component, in disagreement with very well established phenomenology. This puzzle motivated several attempts to construct improved versions of those early works. Among them, one notes the
symmetrized product ansatz by Nyman and Riska [17], which could produce an intermediate range scalar attraction. However, as pointed out by Sternheim and Käbermann [18], there is a violation of baryon number conservation in this ansatz. Exact numerical calculations were also used, which allowed one to evaluate the reliability of the sudden approximation at short distances [19]. Lattice calculations, using a method developed by Manton and collaborators, gave rise to a torus-like baryon density, believed to correspond to the true $B = 2$ ground state and having almost twice the nucleon mass [20]. The scalar potential associated with this configuration does show some medium to long range attraction [21]. However, it is worth recalling that lattice results depend on the definitions adopted for collective coordinates and, as the full treatment is rather difficult, one usually resorts to approximations [22, 23].

In this work we consider the scalar interaction between skyrmions, in order to explore the possibility of obtaining the central attraction at large distances by relaxing some of the constraints present in usual calculations. We employ the sudden approximation because it gives rise to a constructive interaction, in which undeformed nucleons are the main building blocks, as in perturbative calculations. Our presentation is divided as follows. In section 2 we study the asymptotic behaviour of the scalar potential in the standard product ansatz approximation, in order to understand why it does not yield attraction. In section 3 we discuss the construction of alternative solutions, which must be constrained to have the correct baryon number. Finally, in section 4 we analyze a possible solution to the problem, and present concluding remarks.

2 Central potential

The structure of the central potential has been studied recently, in the framework of chiral perturbation theory [14, 24, 25]. In momentum space, the leading contribution has the generic form

$$V_C(t) = -\frac{2}{f_\pi^2 m^2} \left[ f_\pi^2 \left( a_{00}^+ + a_{01}^+ t \right) \right] \sigma(m; t),$$

(1)

where $f_\pi$ is the pion decay constant, the $a_{ij}^+$ are subthreshold coefficients [14] and $\sigma(m; t)$ is the scalar form factor, that depends on both the momentum transferred $t$ and the baryon mass $m$. This form factor is defined generically in terms of the symmetry breaking Lagrangian $L_{sb}$ as

$$\langle N(p') \mid - L_{sb} \mid N(p) \rangle = \sigma(t) \, \bar{u}(p') \, u(p).$$

(2)

In configuration space, eq. (1) becomes

$$V_C(d) = -\frac{2}{f_\pi^2 m^2} \left[ f_\pi^2 \left( a_{00}^+ + a_{01}^+ \nabla^2 \right) \right] \sigma(m; d),$$

(3)

where $d$ is the internucleon distance and $\sigma(m; d)$ is the Fourier transform of $\sigma(m; t)$. In order to allow this result to be compared with the corresponding one in the Skyrme model, we note that, in the large $N_c$ limit, the nucleon and the delta are degenerate and very heavy. In ref. [24], the heavy baryon limit of $\sigma(m; d)$ was considered and found to be

$$\sigma(m \to \infty; d) \to \sigma^{HB}(d) = \frac{9m^6_{\pi}}{128\pi^2} \left( \frac{g_A}{f_\pi} \right)^2 \left[ \frac{d}{dx} \frac{e^{-x}}{x} \right]_1^2,$$

(4)
with $x = m_\pi d$. The central potential is

$$V_{CB}^H(d) = -\frac{2}{f^2\pi m_\pi^2} \left[ \frac{9m_\pi^6 g_\Lambda^2}{128\pi^2} \right] \left[ a_{00}^+ \left( 1 + \frac{2}{x} + \frac{1}{x^2} \right) + 4 m_\pi^2 a_{01}^+ \left( 1 + \frac{3}{x} + \frac{11}{2x^2} + \frac{6}{x^3} + \frac{3}{x^4} \right) \right] e^{-2x} \tag{5}$$

and, at very large distances, it behaves as

$$V_{CB}^H(d) \to -K \left( \frac{e^{-x}}{x} \right)^2. \tag{6}$$

The sign of the constant $K$ is determined by the values of the subthreshold coefficients in the combination $(a_{00}^+ + 4 m_\pi^2 a_{01}^+)$. In Table 1 we display empirical values for the $a_{00}^+$ and it is possible to note that the correct sign of $V_C$ comes mainly from $a_{01}^+$, since $a_{00}^+$ in isolation would give rise to a repulsive interaction.

| Coefficient | ref. [11] | ref. [26] | ref. [27] | ref. [27] |
|-------------|-----------|-----------|-----------|-----------|
| $a_{00}^+ (m_\pi^{-1})$ | -1.46 ± 0.10 | -1.30 ± 0.02 | -1.27 ± 0.03 | -1.15 ± 0.03 |
| $a_{01}^+ (m_\pi^{-1})$ | 1.14 ± 0.02 | 1.35 ± 0.14 | 1.27 ± 0.03 | 1.23 ± 0.03 |
| $K$ (MeV) | 21.6 | 28.5 | 26.5 | 26.2 |

Table 1: Empirical values for the subthreshold coefficients $a_{00}^+$, $a_{01}^+$ and the constant $K$, which determines the intensity of the central potential.

In order to study the central potential in the Skyrme model, we recall that the standard soliton Lagrangian density is written as

$$\mathcal{L} = \mathcal{L}_\sigma + \mathcal{L}_4, \tag{7}$$

where

$$\mathcal{L}_\sigma = \frac{f_\pi^2}{4} \text{Tr}(\partial_\mu U \partial^\mu U^\dagger) + m_\pi^2 \frac{f^2_\pi}{4} \text{Tr}(U + U^\dagger - 2) \tag{8}$$

corresponds to the non-linear $\sigma$ model and

$$\mathcal{L}_4 = \frac{1}{32e^2} \text{Tr} [\partial_\mu U U^\dagger, \partial_\nu U U^\dagger]^2 \tag{9}$$

is the stabilizing term. In these expressions, $e$ is a free parameter, called Skyrme constant, whereas the dynamical variable $U$ is a $2 \times 2$ unitary matrix, given by

$$U = e^{i \hat{\tau} \cdot \hat{\pi} F} = \cos F + i \hat{\tau} \cdot \hat{\pi} \sin F, \tag{10}$$

where $\hat{\tau}$ are the isospin Pauli matrices and $F$ is the chiral angle, whose boundary conditions determine the baryon number of a particular configuration. The function $F$ and the isospin direction $\hat{\pi}$ are related to the pion field $\pi$ of the non-linear $\sigma$ model by $\pi = f_\pi \sin F \hat{\pi}$. 

4
In the $B = 1$ case, a static solution is obtained using the condition $\hat{\tau} = \hat{r}$, the so called hedgehog ansatz, with boundary conditions $F(r = 0) = \pi$ and $F(r \to \infty) = 0$ \cite{8}. The quantization of this baryon is achieved by rotating the static solution with the help of collective coordinates, as a rigid body. This procedure endows the skyrmion with spin and isospin and corresponds to multiplying the pion field by the rigid body rotation matrix $D$,

$$\pi_i \to \pi^q_i = D_{ai} \pi_i.$$  \hspace{1cm} (11)

The matrices $D$ satisfy the completeness relations $D_{ai}D_{aj} = \delta_{ij}, \ D_{ai}D_{\beta i} = \delta_{\alpha \beta}$ and, in the case of nucleons, the correspondence with the ordinary formalism is achieved by using

$$\langle N|D_{ai}|N \rangle = -\frac{1}{3} \langle N|\tau_{\alpha}|N \rangle, \hspace{1cm} (12)$$

$\sigma_i$ being the spin Pauli matrices.

The scalar form factor in the Skyrme model can be obtained directly from eqs. (8) and (10) and reads

$$\sigma_{Sk}(d) = \langle N| - L_{sb}(d) |N \rangle = -m_{\pi}^2 f_{\pi}^2 [\cos F(d) - 1]. \hspace{1cm} (13)$$

On the other hand, the asymptotic form of the chiral angle is determined by $L_{\sigma}$ as \cite{28}

$$F_{\infty}(d) = \left( \frac{3g_{A}m_{\pi}^2}{8\pi f_{\pi}^2} \right) \left( \frac{d}{dx} \frac{e^{-x}}{x} \right) \hspace{1cm} (14)$$

and hence, for large distances, the leading term in eq. (13) yields $\sigma_{\infty}^{Sk}(d) = \sigma^{HB}(d)$. In order to test this relationship further, we write

$$\sigma_{\infty}^{Sk}(d) = m_{\pi}^2 f_{\pi} \langle N| \sqrt{f_{\pi}^2 - \tau_{\alpha} \cdot \tau_{\alpha}} - f_{\pi} |N \rangle \approx \frac{m_{\pi}^2}{2} \pi^2$$

$$= \frac{m_{\pi}^2}{2} \left[ \langle N|\pi^q_{\alpha}|N \rangle \langle N|\pi^q_{\alpha}|N \rangle + \langle N|\pi^q_{\alpha}|\Delta \rangle \langle \Delta|\pi^q_{\alpha}|N \rangle \right]. \hspace{1cm} (15)$$

Using eqs. (11) and (12) in the last expression, one concludes that $N$ and $\Delta$ intermediate states determine respectively $1/3$ and $2/3$ of the total value of $\sigma_{\infty}^{Sk}(d)$. This relative proportion is identical to that found recently in the framework of chiral perturbation theory \cite{25}, indicating that the Skyrme model does provide a rather reliable description of the scalar form factor in the heavy baryon limit.

For systems with $B = 2$, the standard point of departure for constructing approximate solutions is the product ansatz (PA). It uses two undistorted $B = 1$ hedgehog solutions, whose centers are located at two fixed points equidistant from origin along the $z$ axis, so that the hedgehog space coordinates are given by $y = r + d \hat{z}/2$ and $w = r - d \hat{z}/2$. Denoting the composite field by $U(y,w)$, one writes

$$U(y,w) = U(y)U(w). \hspace{1cm} (16)$$

In this configuration, the $B = 2$ condition is automatically fulfilled, for any distance between their centers \cite{29}. As the PA keeps the identities of constituent skyrmions, it allows the direct incorporation of spin and isospin, through collective rotations of individual hedgehogs.
The potential is a function of the distance $d$ and given by

$$V(d) = -\int d^3 r \mathcal{L}_{\text{int}}(r, d\hat{z}) ,$$

where $\mathcal{L}_{\text{int}}$ is obtained by using the field $U(y, w)$ in the Skyrme Lagrangian, eqs. (6-9), and subtracting the self energies $\mathcal{L}[U(y)]$ and $\mathcal{L}[U(w)]$. This potential works well in the isospin-dependent channels, since the OPEP is reproduced for distances larger than 2 fm and it is also possible to identify the roles of $\rho$ and $A1$ mesons [30]. On the other hand, problems occur in the scalar-isoscalar channel, where the interaction is repulsive at all distances, in sharp contradiction with phenomenology.

Using the definitions $F'_y = dF(y)/dr$, $s_r = \sin F(r)$ and $c_r = \cos F(r)$, the central potential is given by

$$V_C^{\sigma}(d) = \frac{2f_{\pi}4\pi}{e} \int_0^\infty dz \int_0^\infty \rho d\rho \left\{ -\frac{3m_\pi^2}{16e^2f_{\pi}^2} (1 - c_y)(1 - c_w) 
+ \left[ \left( F_y'^2 + \frac{s_y^2}{y^2} \right) \left( F_w'^2 + \frac{s_w^2}{w^2} \right) + \frac{2y's_w}{y^2w^2} - (\hat{y} \cdot \hat{w})^2 \left( F_y'^2 - \frac{s_y^2}{y^2} \right) \left( F_w'^2 - \frac{s_w^2}{w^2} \right) \right] \right\} .$$

In order to study its asymptotic structure, we note that the pion fields exist effectively only in the neighbourhood of the hedgehog centers. When the distance $d$ is large the skyrmion located at $(0, 0, d/2)$ is in the presence of the asymptotic region of $U(y)$, we expand $F_y, F'_y$ and $\hat{y} \cdot \hat{w}$ around the point $w = 0$ and write

$$F_y \approx \alpha e^{-m_\pi w_z} \left( 1 + \frac{f_1}{x} + \frac{f_2}{x^2} \right) \frac{e^{-x}}{x} ,$$

$$F_y' \approx -\alpha e^{-m_\pi w_z} \left( 1 + \frac{g_1}{x} + \frac{g_2}{x^2} \right) \frac{e^{-x}}{x} ,$$

$$\hat{y} \cdot \hat{w} \approx \frac{w_z}{\sqrt{\rho^2 + w_z^2}} \left( 1 + \frac{m_\pi \rho^2}{w_z x} - \frac{3m_\pi^2 \rho^2}{2x^2} \right) ,$$

where $f_i, g_i$ are dimensionless polynomials of $w_z \equiv (z - d/2)$ and $\rho$, which are not displayed here. These expressions were tested order by order, by using them in eq. (18) and checking that the potential did had the asymptotic structure, as in eq. (6). We found out that it was necessary to expand $F(y)$ up to order $d^{-2}$, in order to have accurate results.

Replacing eqs. (19-21) into (18), we obtain an asymptotic contribution of the form

$$V_C^{\sigma}(d) \rightarrow -K \left[ 1 + \frac{\alpha_1}{x} + \frac{\alpha_2}{x^2} \right] \frac{e^{-2x}}{x^2} ,$$

for both $\mathcal{L}_\sigma$ and $\mathcal{L}_4$, separately. The values of the parameters $K$ and $\alpha_i$ are displayed in table 2, based on the numerical constants $m_\pi = 139 \text{ MeV}$, $f_{\pi} = 93 \text{ MeV}$ and $e = 4.0$. For the sake of comparison, we also present the values of those parameters in the case of the phenomenological Argonne potential [31].
Table 2: Coefficients of the multipole expansion of $V_C$ for the product ansatz and the Argonne potential, as defined in eq. (22).

Inspecting this table, one notes that the part of the potential due to $\mathcal{L}_\sigma$ is attractive, but is superseded by a repulsive contribution coming from the stabilizing term. The net sign of the potential is, then, the outcome of a large cancellation. On the other hand, the dependence of eq. (22) on $d$ is similar to those of both the perturbative chiral calculation, eq. (8), and of the phenomenological Argonne potential. We stress that this correct geometry is a general feature of the model, because it depends only on the form of the $B = 1$ solution, and not on the specific ansatz used to obtain the $B = 2$ result. In fig. 1 we display the ratios between the full and asymptotic PA potentials, as given by eqs. (18) and (22), with the purpose of illustrating their convergence. The interplay between the attractive contribution from $\mathcal{L}_\sigma$ and the repulsive one from $\mathcal{L}_4$ can also be seen in fig. 2, where we present the function $dV_C^{PA}(d)/dz$, corresponding to the integrand in $z$ of expression (18), for several values of $d$. One notes that the contributions in the neighbourhood of the skyrmion centers are large and positive but, on the other hand, a negative region develops as the distance $d$ increases.

These features of the central potential allow us to identify clearly the stabilizing term as the responsible for its repulsive character. Therefore, mechanisms which can reduce the importance of $\mathcal{L}_4$ may help in producing an attractive interaction. In the next section we discuss a class of such mechanisms, associated with deformations of the QCD vacuum.

3 Constructing $B = 2$ solutions

We consider here $B = 2$ solutions, constructed by using the hedgehog $B = 1$ skyrmions as building blocks, in the framework of the sudden approximation. In general, an ansatz is a prescription of the form

$$U(y, w) = f [U(y), U(w)],$$

where $f$ is a function, chosen according to physical criteria. The construction of such a function should follow some guidelines:

1. the baryon number of the composite configuration must be two for all distances $d$;
2. the composite pion field must have the correct quantum numbers, being pseudoscalar, isovector and odd under G-parity;
3. the composite Lagrangian must be chiral symmetric, even under G-parity and invariant under the exchange of the two constituent skyrmions.

The standard constructive approximate solution to the $B = 2$ system is based on the PA, as discussed in the previous section. In this approach, the composite pion field, obtained from
Figure 1: Ratios between the multipole expansion and the exact numerical result for the scalar potential (solid) and separate contributions of $L_\sigma$ (dashed) and $L_4$ (dotted).

eqs. (10) and (16), is given by

$$P_{pa} = \frac{1}{f_\pi} (\sigma_y \pi_w + \sigma_w \pi_y - \pi_y \times \pi_w),$$

(24)

where $\pi_r$ is the pion field of the hedgehog with coordinate $r$ and $\sigma_r \equiv f_\pi \cos F(r)$. The function

$$S_{pa} = \frac{1}{f_\pi} (\sigma_y \sigma_w - \pi_y \cdot \pi_w),$$

(25)

is the composite analogous of $\sigma$ and satisfies $S_{pa}^2 + P_{pa}^2 = f_\pi^2$.

The field $P_{pa}$ has a rather serious drawback as a candidate for the pion field, namely that it contains an azimuthal term which is both even under G-parity and antisymmetric under hedgehog exchange. Hence it does not have good pion quantum numbers, violating requirements 2 and 3 stated above.

This motivated us to try to understand whether this problem could be responsible for the absence of attraction found in the central potential. We considered several alternative possibilities, inspired in the PA. The basic idea is to propose a composite field $P$, use it to define a function $S$ by

$$S^2 = f_\pi^2 - P^2,$$

(26)

construct the unitary field as

$$U = [S + i \tau \cdot P] / f_\pi,$$

(27)
and feed it into the Skyrme Lagrangian. We begin by describing briefly some unsuccessful attempts, in order to prevent readers from repeating them.

The simplest exchange-symmetric ansatz would be the average $P = (\pi_y + \pi_w)/2$. However, when $d = 0$, one has $F_y = F_w = F_r$ and hence $P = f_\pi \sin F_r \hat{r}$ corresponds to a $B = 1$ field, which must be disregarded.

This suggests that, in order to obtain $B = 2$, it is mandatory to mix $\pi$ and $\sigma$. In the case of the PA, which yields $B = 2$ at all distances, we note that the chiral constraint between $P_{pa}$ and $S_{pa}$ allows one to write

$$U_{pa} = \left[ S_{pa} + i \tau \cdot P_{pa} \right]/f_\pi \equiv e^{-i \tau \cdot u} F_{pa},$$

where $u$ is a unit vector, taken as pointing always away from the origin of the coordinate system, and $F_{pa}$ is a profile function. In fig. 3 we display the behaviour of this angle along the axes $z$ and $\rho$, for various values of the internucleon distance $d$. The solid lines correspond to the case $d = 0$, which is spherically symmetric and it is possible to see that, along both directions, the chiral angle varies smoothly from $2\pi$ at the origin to 0 at infinity. In the case $d = 0.5$ fm, shown in dotted lines, one notes that a discontinuity has appeared along the $\rho$ axis. This discontinuity increases with distance and, at $d_{crit} = 0.86$ fm, the chiral angle is such that $F_{pa}(\rho = 0, z \to 0) = 2\pi$ and $F_{pa}(\rho \to 0, z = 0) = 0$. Therefore, at this critical point, it is more natural to set $F_{pa}(0,0) = 0$ and to work with two separate solutions, such as illustrated by the

Figure 2: Integrand in $z$ of the scalar potential $V_C(d)$, for (a) $d = 1$ fm, (b) $d = 3$ fm, (c) $d = 5$ fm, (d) $d = 10$ fm; vertical axis: arbitrary unity.
Figure 3: Profile function $F$ for the product ansatz, in unities of $\pi$, along the $z$ (left) and $\rho$ (right) axes, for various values of $d$.

dashed and dot-dashed lines, corresponding to 0.9 and 2.0 fm, respectively. This suggests that, from $d_{\text{crit}}$ onwards, each of the interacting skyrmions acquires a considerable individuality.

The combination

$$P = \frac{1}{f_\pi} (\sigma_y \pi_w + \sigma_w \pi_y)$$

(29)
is interesting, for it has an explicit physical meaning. As the function $\sigma(r)$ is associated with the quark condensate that surrounds the baryon labeled by $r$, this field $P$ represents each skyrmion immersed in the distorted vacuum of the other one. The condition (26) allows one to determine $S$ up to a sign. In the case $B = 1$ the field $\sigma$ changes sign when one goes from infinity to the origin and the same happens when $B = 2$. The sign of $S$ is also important and, in order to fix it, we note that the behaviours of eqs. (24) and (29) along the $z$ axis are identical, since the azimuthal component vanishes. We then forced the condition $S = S_{pa}$ along this axis. However, this ansatz, based on eq. (29), gives rise to a baryon number which varies with $d$, as shown in fig. 4, and had to be abandoned.

This discussion illustrates the fact that it is not trivial to build an ansatz with a good topology. We thus decided to adopt simultaneously the pion field as given by eq. (29) and the function $S_{ap}$ of the PA, eq. (25), for its topology is automatically correct. With this option, the unitarity constraint reads

$$S_{ap}^2 + P^2 = f_\pi^2 \eta^2,$$

(30)

where

$$\eta = \sqrt{1 + \left[(\pi_y \cdot \pi_w)^2 - \pi_y^2 \pi_w^2\right]/f_\pi^4}$$

(31)
and the pion field becomes in fact $P/\eta$. This form for the dynamical variable is the same as that proposed by Nyman and Riska, in their symmetrized product ansatz [17]. This ansatz has a topology similar to the PA, as illustrated in fig. 3. The corresponding baryon number density is given in appendix A and, in the classical case, yields $B = 2$ for all distances when integrated over space, as shown in fig. 5.

4 Results and conclusions

In order to derive the potential, we use the quantized fields of eq. (11), obtained by rotating the constituent skyrmions. This idea of rotating individual hedgehogs corresponds to an approximation and deserves some attention. The quantization of a hedgehog, as discussed in sect. 2, amounts to multiplying the classical field by the matrix $D$, which depends on three free parameters. In the case $B = 1$, this procedure does not change the baryon current. This can be seen by writing the baryon density for quantized fields as

$$B^0 = -\frac{1}{12\pi^2} \epsilon_{abc} \epsilon_{\alpha\beta\gamma} \frac{1}{\sigma} \partial_a D_{\alpha i} \pi_i \partial_b D_{\beta j} \pi_j \partial_c D_{\gamma k} \pi_k$$

and using the result

$$D_{\alpha a} D_{\beta b} = \frac{1}{3} \delta_{\alpha\beta} \delta_{ab} + \frac{1}{2} \epsilon_{\alpha\beta\gamma} D_{\gamma c} \epsilon_{cab} + \text{isotensors}$$

in order to obtain

$$B^0 = -\frac{1}{12\pi^2} \epsilon_{ijk} \epsilon_{abc} \frac{1}{\sigma} \partial_a \pi_i \partial_b \pi_j \partial_c \pi_k .$$
This shows that the baryon density is the same for both quantized and classical fields.

Analogously, in the case $B = 2$, quantization would require a matrix $\bar{D}$, depending on six collective coordinates. However, the determination of this general matrix may prove to be very difficult and, in the spirit of the the sudden approximation, one normally uses $\bar{D} \approx D^{(y)} I^{(w)} + I^{(y)} D^{(w)}$, where $I$ is an identity matrix and $D^{(y)}, D^{(w)}$ are operators over the skyrmions labeled by $y$ and $w$ respectively. The price one pays for this approximation is that it leads to a quantized baryon number which depends on $D^{(y)}$ and $D^{(w)}$. This happens because the relation equivalent to eq. (33) does not hold for the approximate matrix $\bar{D}$ and hence does not represent a major shortcoming for the symmetrized ansatz (SA). Indeed, as pointed out by Sternheim and Kälbermann [18], this poses problems for short distances only.

A collective rotation of the pion field $P$, as in the $B = 1$ case, would leave $S/\eta$ unmodified, as a classical function. However, this would also mean to treat the scalar product $\pi_y \cdot \pi_w$ as a classical quantity and would lead to serious contradictions, for the OPEP content of the isospin dependent channels relies on the quantum character of such a scalar product in eq. (25).

Therefore, the individual rotation of each pion field is more consistent with a constructive approach, although not free of problems. In principle, every pion field $\pi$ in the composite Skyrme Lagrangian should be quantized. When applying this prescription to the dynamical variable of the SA, one has to deal with the functions $\eta^{-2}$ and $\eta^{-4}$, which depend on pion fields, coupled to operators $D$. The meaning of the quantized $\eta^{-2}$ is that of a power series in $D$, which involves products of arbitrary numbers of these matrices and hence can only be handled by resorting to truncation. With this limitation in mind, we treat $\eta^{-2}$ as a polynomial in $\pi$ and thus its expectation value between two-nucleon states can be evaluated without ambiguities.
In order to test the implications of this assumption, in the sequence we present results with two versions of $\eta$, namely, a classical one,

\[ \eta_c^{-2} = \left\{ 1 - \left[ 1 - (\hat{y} \cdot \hat{w})^2 \right] s_y s_w \right\}^{-1}, \]  

and a quantized one, truncated at the first order in the $D$ expansion, given by

\[ \langle NN|\eta_q^{-2}|NN \rangle = \left\{ 1 - s_y s_w \right\}^{-1} \approx \left\{ 1 - \frac{2}{3} s_y s_w \right\}^{-1}. \]  

Replacing the pion field of the symmetrized ansatz into the interaction Lagrangian used to calculate the potential, one has

\[ L_{int} = L_S + D_{\alpha \beta} D_{\alpha \beta} L_V, \]  

where the labels $S$ and $V$ stand respectively for isoscalar and isospin dependent parts of $L_{int}$. Using this result in eq. (17), one gets

\[ V(d) = V_C + \tau^{(y)} \cdot \tau^{(w)} \left[ \sigma^{(y)} \cdot \sigma^{(w)} V_{SS} + S_{12} V_T \right], \]  

where $V_C$, $V_{SS}$ and $V_T$ are the usual central, spin-spin and tensor components. All terms receive both G-parity odd and even contributions.

The G-parity odd components of spin-spin and tensor terms of the potential are shown in fig. 6, for the two possible choices of $\eta$, compared to the PA and pure OPEP results. One sees that all curves coincide for distances larger than 2 fm, indicating that all ansätze reproduce asymptotically the OPEP. The results for the G-parity even terms are of minor importance here, as we are interested in the long range behaviour of the potential, but they are included for completeness in fig. 7. One should note that in the case of $\eta_c$, the potentials present a singularity at $d \sim 0.6$ fm, due to a root of $\eta_c$.

Results for the scalar component $V_C$ are presented in figs. 8 and 9. In the former we display the behaviour of the PA (left) and the predictions from the SA with $\eta = 1$ (right), which is non-unitary and considered just for pedagogical purposes. Inspecting it one learns that the SA includes a contribution from $L_2$, that was not present in the PA. Moreover the contribution from $L_4$ is negative, and so is the net result for $V_C$.

The two valid options for the SA considered here, based on $\eta_c$ and $\eta_q$, are given in fig. 9. In both cases we observe that the unitarity constraint restores the repulsion due to $L_4$, but in such a way that the net result is asymptotically attractive. On the other hand, the amount of overall attraction found in the SA depends on the specific quantization prescription adopted. At very large distances, the curves corresponding to $\eta_c$ and $\eta_q$ have the same geometry and yield respectively the following approximate values for the intensity of the potential: $K_c = 14$ MeV and $K_q = 57$ MeV. Comparing them with the empirical values in table 1, it is possible to see that predictions from the SA are qualitatively reasonable.

In summary, we have shown that the SA provides the correct baryon number for the two-nucleon system in the Skyrme model, as well as attractive central $NN$ potentials. The correct
Figure 6: Comparison among Skyrme model G-parity odd spin-spin (left) and tensor (right) potentials from symmetrized ansatz, with classical (dotted) and quantized (dashed) versions of $\eta$, from product ansatz (long dashed) and OPEP (solid).

Figure 7: G-parity even spin-spin (left) and tensor (right) potentials from symmetrized ansatz, with classical (dotted) and quantized (dashed) versions of $\eta$, and from product ansatz (long dashed).

quantitative feature is somewhere between the values obtained for the two versions of the normalization function $\eta$.

We conclude that it is indeed relevant to the central potential to eliminate the term with a wrong G-parity from $P_{pa}$. We expect that a deeper and more careful study of the quantization procedure will lead to a more accurate evaluation of the amount of attraction coming from the SA.

We would like to thank the hospitality of the Nuclear Theory Group, in the University of Washington, and of the Division de Physique Théorique, in the Institute de Physique Nucléaire/Orsay, where part of this work was performed.
A Appendix: The baryon number

The explicit calculation of the zero-component of the baryon current yields

$$B^0 = B_1^0 + B_2^0,$$  \hspace{1cm} (39)

where

$$B_1^0(\mathbf{r}; d) = - \frac{1}{2\pi^2 \eta^2} \left( c_y \frac{s_w}{w} + c_w \frac{s_y}{y} \right)^2 \left( F'_y + F'_w \right),$$

$$B_2^0(\mathbf{r}; d) = - \frac{1}{2\pi^2 \left( c_y c_w - (\hat{\mathbf{y}} \cdot \hat{\mathbf{w}}) s_y s_w \right) \eta^2} \left( c_y \frac{s_w}{w} + c_w \frac{s_y}{y} \right),$$

$$\cdot \left\{ \left( 1 - (\hat{\mathbf{y}} \cdot \hat{\mathbf{w}})^2 \right) \left[ c_y c_w \left( F'_y - \frac{s_y}{y} \right) \left( F'_w - \frac{s_w}{w} \right) - (\hat{\mathbf{y}} \cdot \hat{\mathbf{w}})^2 F'_y F'_w \right] \right\}$$

$$- \left[ \frac{s_y s_w}{\eta^2} J_y \left( \left( c_y \frac{s_w}{w} + c_w \frac{s_y}{y} \right) \left( c_w s_y + (\hat{\mathbf{y}} \cdot \hat{\mathbf{w}}) c_y s_w \right) + \left( 1 - (\hat{\mathbf{y}} \cdot \hat{\mathbf{w}})^2 \right) s_y c_y \left( F'_w - c_w \frac{s_w}{w} \right) \right) \right] - [y \leftrightarrow w],$$

with $J_y = \left( (\hat{\mathbf{y}} \cdot \hat{\mathbf{w}})^2 - 1 \right) c_y F'_y s_w + (\hat{\mathbf{y}} \cdot \hat{\mathbf{w}}) \left( s_y \frac{sw}{w} - (\hat{\mathbf{y}} \cdot \hat{\mathbf{w}}) s_w \frac{sw}{y} \right)$.

The numerical integration of $B_2^0$ is tricky due to the presence of the function $S$ in the denominator. Results are shown in fig. 5 as functions of separation distance $d$. It shows that the SA presents the correct topology for the $NN$ system.
