Abstract

Tau is one of several proteins associated with frontotemporal dementia (FTD). While knowing which protein is causing a patient’s disease is crucial, no biomarker currently exists for identifying tau in vivo in FTD. The objective of this study was to investigate the potential for the promising [18F]MK-6240 positron emission tomography (PET) tracer to bind to tau in vivo in genetic FTD.

We enrolled subjects with genetic FTD, who constitute an ideal population for testing because their pathology is already known based on their mutation. Ten participants (three with symptomatic P301L and R406W MAPT mutations expected to show tau binding, three with presymptomatic MAPT mutations, and four with non-tau mutations who acted as disease controls) underwent clinical characterization, tau-PET scanning with [18F]MK-6240, amyloid-PET imaging with [18F]NAV-4694 to rule out confounding Alzheimer’s pathology and high-resolution structural magnetic resonance imaging (MRI).

Tau-PET scans of all three symptomatic MAPT carriers demonstrated at least mild [18F]MK-6240 binding in expected regions, with particularly strong binding in a subject with an R406W MAPT mutation (known to be associated with Alzheimer’s like neurofibrillary tangles - NFTs). Two asymptomatic MAPT carriers estimated to be five years from disease onset both showed modest [18F]MK-6240 binding, while one approximately thirty years from disease onset did not exhibit any binding. Additionally, four individuals with symptomatic FTD caused by a non-tau mutation were scanned (two C9orf72; one GRN; one VCP): [18F]MK-6240 scans were negative
for three subjects, while one advanced C9orf72 case showed minimal regionally non-specific binding. All ten amyloid-PET scans were negative. Furthermore, a general linear model contrasting genetic FTD subjects to a set of 83 age-matched controls showed significant binding only in the MAPT carriers in selected frontal, temporal and subcortical regions.

In summary, our findings demonstrate mild but significant binding of MK-6240 in amyloid-negative P301L and R406W MAPT mutation subjects, with higher SUVR in the R406W mutation associated with the presence of NFTs, and little non-specific binding. These results highlight that a positive $^{18}$F]MK-6240 tau-PET does not necessarily imply a diagnosis of Alzheimer’s disease and point towards a potential use for $^{18}$F]MK-6240 as a biomarker in certain tauopathies beyond Alzheimer’s, although further patient recruitment and autopsy studies will be necessary to determine clinical applicability.

Introduction

Frontotemporal dementia (FTD) comprises a heterogeneous group of proteinopathies which are all associated with involvement of the frontal and temporal lobes, but may manifest distinct clinical presentations.\(^1\) Importantly, several different proteins are known to pathologically aggregate in FTD, including but not limited to TAR DNA-binding protein 43 (TDP-43) and tau.\(^2\) At present, it is impossible to identify \textit{in vivo} which protein is causing a given case of sporadic FTD; this is problematic as any future disease-modifying treatments will likely come from specifically targeting the underlying pathology rather than clinical syndromes.\(^3\) The only way to definitively determine the pathological subtype of frontotemporal lobar degeneration (FTLD) currently is by autopsy, unless the patient has a genetic form of the disease.\(^4\) Approximately 15-30\% of FTD cases are caused by an autosomal dominant, full penetrance mutation for which the pathology is presumed. The \textit{microtubule-associated protein tau} (MAPT) mutation is the only one known to cause FTD due to a pathological aggregation of tau; other mutations such as \textit{chromosome 9 open reading frame 72} (C9orf72) expansion, \textit{progranulin} (GRN), and \textit{valosin-containing protein} (VCP) lead to FTD secondary to accumulation of TDP-43.\(^5\)
A molecular diagnostic marker capable of reliably detecting the pathology in vivo in FTD could advance understanding of the distribution and progression of pathology in the disease, enable earlier and more accurate diagnosis and prognostication of FTD, and enhance clinical trials of specific disease-modifying drugs by enabling selection of patients by pathology.3, 6

Tau-PET imaging is currently being explored as a promising method of identifying the tau protein in vivo.7 However, developing a reliable tracer is proving to be challenging – in part due to the inherent heterogeneity of tau. In fact, there are six different isoforms of the tau protein, and these can adopt different conformations, leading to various tauopathies.8 The characteristic tau pathology found in Alzheimer’s disease consists of neurofibrillary tangles (NFTs) comprised of all six tau isoforms. By contrast, tau in FTLD is variable: the classic inclusions in Pick’s Disease are Pick bodies composed mainly of 3R tau, whereas the brains of patients affected by Progressive Supranuclear Palsy and Corticobasal Syndrome chiefly contain 4R tau.8 In genetic FTD secondary to a MAPT mutation, tau pathology is also heterogeneous: patients typically have predominantly 4R pathology, but may also form NFTs like in Alzheimer’s disease depending on the location of the mutation.9

The most well-characterized tau-PET tracers have thus far demonstrated limited clinical utility for detecting tau outside of Alzheimer’s disease. For example, [18F]THK-5351 binding was shown to be significantly modulated by MAO-B.10 Flortaucipir ([18F]AV-1451) has been suggested to have limited sensitivity and specificity in non-Alzheimer’s tauopathies.11 It has been shown in vivo to bind significantly to specific MAPT mutations known to engender NFT pathology;12-14 however, it has also been found to bind to semantic variant primary progressive aphasia (svPPA)15, 16 and C9orf72 mutation17, both of which are predominantly associated with TDP-43 pathology as opposed to tau. Post-mortem studies, however, have not revealed flortaucipir binding to TDP-43 in either svPPA18 or C9orf7219, and have further demonstrated that the tracer has limited reliability in non-Alzheimer’s tauopathies20 other than MAPT mutations that have NFT pathology resembling Alzheimer’s disease21, 22. [11C]PBB3, another first generation tracer, has limited utility due to technical issues;23, 24 however, the newer [18F]PM-PBB3 tracer has returned favourable results thus far both in terms of eschewing those limitations25 and potential applications in 3R and 4R tauopathies26, although further studies will
be required. Finally, another recent tracer is [18F]PI-2620, which has shown distinct binding in 4R tauopathies\textsuperscript{27}.

The recently developed [\textsuperscript{18}F]MK-6240 tau-PET tracer\textsuperscript{28} is one of the second-generation tracers that has shown promising results not only \textit{in vitro} and in animals,\textsuperscript{29, 30} but also in human studies featuring healthy controls as well as subjects with mild cognitive impairment and Alzheimer's disease.\textsuperscript{31-33} Furthermore, MK-6240 has exhibited strong specificity and sensitivity for tau without the influence of monoamine oxidase (MAO).\textsuperscript{34} While off-target binding to melanin and meninges is notable, and mild off-target binding to intraparenchymal hemorrhage is observed as well, there is no off-target binding to key brain regions such as the basal ganglia as exhibited by certain other tracers.\textsuperscript{34} However, the effectiveness of MK-6240 in non-Alzheimer’s tauopathies remains to be determined.

The objective of this work is to characterize the binding of the MK-6240 tracer in FTD. In order to do this, we have scanned patients with genetic FTD. These patients constitute an ideal study population as their pathology may reasonably be anticipated in advance: individuals with a \textit{MAPT} mutation are known to have FTLD with tau accumulation and thus should be expected to show MK-6240 binding; conversely, participants with mutations such as \textit{C9orf72}, \textit{GRN}, and \textit{VCP} which cause FTD with TDP-43 pathology act as tau-free disease controls who are not expected to show MK-6240 binding and should resemble a group of cognitively normal controls.\textsuperscript{5}

\section*{Methods}

\subsection*{Participants}

Subjects were recruited between April 2019 and February 2020 from the McGill University Health Centre (MUHC) as well as from a network of collaborating sites in Quebec and Ontario. All participants either have symptomatic definite FTD confirmed by genetic testing or are presymptomatic carriers of the \textit{MAPT} mutation. Each subject was brought to the Montreal Neurological Institute where they underwent cognitive testing for screening purposes, an MRI
study, tau-PET imaging with $[^{18}\text{F}]$MK-6240, and an amyloid-PET scan with $[^{18}\text{F}]$NAV-4694 (AZD-4694) to rule out confounding Alzheimer's disease pathology. The FTLD-Clinical Dementia Rating (FTLD-CDR) was also completed in order to assess severity status, with global scores calculated as per Miyagawa et al (see Supplementary Table 1 for more detail). The protocol was approved by the MUHC's research ethics board, and informed written consent was obtained from each participant or an approved surrogate decision maker.

**Imaging Protocol**

All participants underwent high-resolution 3D T1-weighted magnetic resonance imaging (MRI) with 1mm isometric slice thickness on a 3T Siemens scanner. PET scans were acquired on a high-resolution research tomograph (HRRT) Siemens scanner. $[^{18}\text{F}]$MK-6240 images were obtained 90-110 minutes following administration of 185 MBq of the tracer, and were reconstructed using an ordered-subsets expectation maximization (OSEM) algorithm on a 4D volume with 4 frames (4 x 300s). $[^{18}\text{F}]$NAV-4694 scans were performed 40-70 minutes after intravenous injection of 185 MBq of the tracer, and were reconstructed using the same OSEM algorithm on a 4D volume with 3 frames (3 x 600s). A 6-minute transmission scan for attenuation correction was completed with a rotating Cesium-137 point source after each PET scan, and images were subsequently corrected for dead time, decay, and random and scattered coincidences.

Images were subsequently analyzed in order to extract standardized uptake value ratios (SUVRs). The processing methods, using an in-house pipeline based around Advanced Normalization Tools (ANTS; http://stnava.github.io/ANTs/), have been described in prior publications. Briefly: the MRI is first segmented and non-uniformity corrected. Next, the T1-weighted image is non-linearly registered to the ADNI template space. A rigid body transformation subsequently brings the native PET image into the native T1 space. Following this, the scans are masked using an unbiased tissue mask generated with version 12 of SPM (https://fil.ion.ucl.ac.uk/spm/) in order to minimize off-target binding to meninges, and then images are spatially smoothed to yield a resolution of 8mm full-width at half maximum. Finally, SUVRs are calculated using the inferior cerebellar grey matter as a reference region, in accordance with previously-established methods. For comparison, unmasked scans can be
found in the supplementary materials (Supplementary Figs. 1-3), as can partial volume-corrected images using region-based voxel-wise correction\textsuperscript{44} (Supplementary Figs. 4-6).

**Statistical Analyses**

Next, a general linear model was constructed using all ten FTD cases and 83 age-matched cognitively normal individuals from another local study (TRIAD cohort\textsuperscript{38}) with the diagnostic outcome as a dependent variable (binomial distribution), and MK-6240 SUVR as an independent variable, using age and sex as covariates. Correction for multiple comparisons was done using Random Field Theory (RFT),\textsuperscript{45} and the model was implemented using VoxelStats\textsuperscript{46}.

Finally, hippocampal volume was measured on MRI with brain parcellation done with Freesurfer (https://surfer.nmr.mgh.harvard.edu) and version 12 of SPM used for the general tissue-based segmentation. The results were adjusted for intracranial volume based on all subjects, including the 83 age-matched cognitively normal individuals, using a previously established method\textsuperscript{47}. More detail about these processing methods and calculations can be found in the Supplementary materials.

**Data availability**

The data that support the findings of this study are available from the corresponding author, upon reasonable request.

**Results**

**Participants**

Ten individuals are included in these results: three with symptomatic *MAPT* mutations, three asymptomatic *MAPT* carriers, and four with symptomatic TDP-43 mutations. Table 1 provides details about patient demographics, mutations, and disease characteristics.
Symptomatic MAPT carriers

All three patients with a symptomatic MAPT mutation showed some degree of MK-6240 binding, as depicted in Fig. 1. Fig. 1a is a 71 year old man with clinically advanced behavioral variant FTD (FTLD-CDR= 2) due to a P301L MAPT mutation; the MK-6240 scan demonstrates binding of the tracer with SUVRs above 2 in regions classically associated with tau pathology in the disease: frontal lobes, temporal lobes, and basal ganglia bilaterally, as well as in the parietal lobes. Fig. 1b is a 67 year old man with behavioral variant FTD (FTLD-CDR = 2) also due to a P301L MAPT mutation; the MK-6240 scan reveals mild binding of the tracer in similar regions as in patient 1, albeit with lower SUVRs in the 1.4 to 1.5 range. Fig. 1c is a 60 year old woman with clinically mild behavioral variant FTD (FTLD-CDR = 1) due to a R406W MAPT mutation; marked binding of the MK-6240 tracer with SUVRs above 4 is observed in the anteromedial temporal lobe bilaterally. In addition, all three cases showed brain atrophy in a typical bvFTD profile (Supplementary Fig. 7).

Asymptomatic MAPT Carriers

Fig. 2 features the MK-6240 scans from three asymptomatic P301L MAPT mutation carriers. Fig. 2a is a 30 year old woman approximately three decades before expected disease onset (estimated based on the difference with the mean age of onset in the family); the MK-6240 scan reveals no binding in the brain, although some off-target binding to meninges is observed. In Fig. 2b, an asymptomatic 57 year old woman who tested positive for the P301L MAPT mutation and is one year from expected onset of symptoms demonstrates very mild binding of MK-6240 with SUVRs around 1.4 particularly in the frontal and temporal lobes as well as the basal ganglia. Of note, this subject’s MRI revealed temporal lobe atrophy (Supplementary Fig. 8). Fig. 2c is a 52 year old male carrier 5 years from expected symptom onset; scattered foci of MK-6240 binding with SUVRs up to 1.4 are observed throughout the cortex.

Non-tau Mutations

Fig. 3 includes the negative MK-6240 scans obtained from four patients with a symptomatic non-Tau mutation. Fig. 3a is a 51 year old man with a mildly symptomatic mixed behavioral...
variant FTD and semantic variant primary progressive aphasia secondary to a VCP mutation (FTLD-CDR = 0.5). Fig. 3b shows a 41 year old man with early behavioral variant FTD due to a C9orf72 mutation (FTLD-CDR = 0.5). Fig. 3c is a 44 year old man with moderately advanced behavioral variant FTD in the context of a C9orf72 mutation (FTLD-CDR = 2). Fig. 3d is a 61 year old man with behavioral variant FTD due to a $GRN$ mutation (FTLD-CDR = 1). Three of these subjects did not show any tracer binding in the brain, while the subject in Fig. 3c demonstrated some binding in the frontal lobe and cerebellum at the frontier with the meninges, as well as scattered mild binding throughout the cortex. Of note, the subjects in Figs. 3a and 3d exhibit clear evidence of temporal and/or frontal atrophy on MRI despite the absence of tau binding. The mildly symptomatic subject in Fig. 3b shows more subtle volume loss (Supplementary Fig. 9).

**Amyloid-PET**

All ten subjects had negative amyloid-PET scans with NAV-4694, thereby ruling out the possibility of Alzheimer's disease pathology driving tau positivity.

**FTD versus Cognitively Normal Model**

Fig. 4 shows a general linear model comparing RFT-corrected MK-6240 binding in FTD subjects to 83 age-matched cognitively normal controls. A statistically significant difference in MK-6240 SUVR can be seen between the $MAPT$ mutation group (including both presymptomatic and symptomatic subjects) and the cognitively normal group at three regions of interest (ROI): right inferior temporal lobe, left medial orbitofrontal lobe, and left putamen. In addition, the non-tau FTD group did not show any significant differences with the cognitively normal group. A section-wise summary of the averaged SUVRs across all 83 controls showing no significant binding can be found in the supplementary materials (Supplementary Fig. 10).

**Hippocampal Atrophy versus Temporal Meta-ROI SUVR**

Fig. 5 displays hippocampal atrophy maps for all ten subjects and plots hippocampal volume against MK-6240 binding in the temporal meta-ROI. Of note, all three symptomatic MAPT cases exhibit lower hippocampal volume and higher SUVR than any other subjects. Furthermore, the
graph does not follow a direct linear relationship, which suggests the binding is not simply being driven by atrophy.

Discussion

This study describes $[^{18}\text{F}]\text{MK-6240}$ tau-PET scans in a cohort of ten genetic FTLD patients, including five distinct mutations. Our results represent some of the first MK-6240 scans in vivo in a non-Alzheimer’s tauopathy. We found MK-6240 binding in symptomatic $\text{MAPT}$ patients predominantly in brain regions known to manifest pathology in FTLD. Binding was unexpectedly present in the parietal lobes of the two symptomatic $P301L\text{ MAPT}$ cases (Figs. 1a-b); however, although the parietal lobes are not classically implicated in the $\text{MAPT}$ mutation, both of these patients were clinically advanced, and pathology is known to extend throughout the brain later in the disease course. In addition, notably higher SUVR values were obtained in the participant with an $R406W\text{ MAPT}$ mutation compared to milder binding in subjects with a $P301L\text{ MAPT}$ mutation. Furthermore, we detected subtle binding of the tracer in presymptomatic $P301L\text{ MAPT}$ carriers within five years of estimated disease onset. No significant MK-6240 binding was observed in three of the four symptomatic patients with non-tau mutations ($C9orf72$, $\text{GRN}$, and $\text{VCP}$). There was mild scattered uptake in an advanced case of $C9orf72$ mutation. While this could represent off-target binding, it is difficult to interpret without autopsy confirmation in a clinically advanced case of $C9orf72$, which is known to accumulate tau pathology in some patients.

Furthermore, the presence of statistically significant stronger binding was detected in $\text{MAPT}$ mutation compared to 83 age-matched cognitively normal individuals in three key regions of interest (right inferior temporal lobe, left putamen, and left medial orbitofrontal lobe). There was no significant difference between the non-tau mutations and the controls. Finally, the symptomatic $\text{MAPT}$ subjects all demonstrated more extensive hippocampal atrophy with stronger tracer binding than the other study participants.

A large body of pre-existing evidence, including the tracer’s previous success in Alzheimer’s disease, confirms MK-6240 binding to tau specifically in the NFT conformation. In fact, the
only autoradiography study conducted thus far with MK-6240 on human postmortem brain tissue concluded by proposing “that MK-6240 strongly binds to neurofibrillary tangles in Alzheimer disease but does not seem to bind to a significant extent to tau aggregates in non-Alzheimer tauopathies”. The tracer preferentially binding to NFTs in particular could explain our finding of considerably stronger binding in a participant with a mildly symptomatic \( R406W \) MAPT mutation (Fig. 1c), as \( R406W \) is one of the rare mutations in exon 13 of the MAPT gene that engenders Alzheimer’s-like NFT pathology.\(^{31}\) However, our findings in amyloid-negative subjects with a \( P301L \) MAPT mutation (Figs. 1a-b, Figs. 2b-c) are more difficult to explain. \( P301L \) is a mutation in exon 10 of the MAPT gene which causes accumulation of 4R tau, though 3R tau as well as wildtype tau are also present\(^9\); \( P301L \) neuropathological case series have mainly described mini-Pick bodies, twisted tau filaments, and pretangles.\(^{52,53}\) As such, whether MK-6240 was binding to sparse NFTs in these patients, to pretangles, or to something else entirely remains ambiguous. Further patient recruitment for in vivo scanning, and especially additional autopsy studies of MAPT patients, will be essential for clarification.

Of note, the aforementioned MK-6240 autoradiography study featured one subject with a \( P301L \) MAPT mutation, in whom no MK-6240 binding was detected.\(^{34}\) The apparent discrepancy between this finding and our results may be explained by the fact that only a single \( P301L \) MAPT patient was autopsied, and \( P301L \) MAPT can be a heterogeneous disease.\(^{53}\) This further illustrates the necessity for larger autopsy studies of this population.

While the ability of MK-6240 to bind to conformations of tau other than NFTs requires additional investigation, the negative scans obtained in control subjects with symptomatic mutations typically associated with FTLD-TDP43 in our study imply a promising degree of specificity for tau (Fig. 3; with the caveat of the aforementioned questionable binding in Fig. 3c). The tau-PET tracer flortaucipir (\(^{[18}\)F]AV-1451) provides a useful comparison as it is well-studied and also binds to NFTs in vivo, making it very effective in Alzheimer's disease and MAPT mutations like \( R406W \). However, some studies indicate flortaucipir exhibits off-target binding, including in svPPA (which is not completely understood). Our results therefore suggest MK-6240 may have a higher specificity for tau, although this remains to be confirmed in a larger study of MK-6240 including PPA cases.
Regarding results in presymptomatic MAPT carriers, one should keep in mind that the estimated years to onset (EYO) measure is only partially correlated with actual age at onset\(^4\); therefore it is not possible to know how close our participants truly are to their onset without longitudinal follow-up. The mild MK-6240 binding observed in presymptomatic MAPT carriers in brain regions known to accumulate tau pathology in FTLD (e.g. basal ganglia\(^9\), cingulate cortex\(^18\)), as seen in Fig. 2, is nevertheless an encouraging finding from this study. The utility of tau-PET in presymptomatic patients has previously been questioned, as tau accumulation is considered to be temporally related to symptom burden.\(^6\) However, a recent study proposed that MK-6240 may be an effective biomarker in preclinical Alzheimer's disease,\(^54\) and our findings suggest that the tracer may also be useful in some MAPT mutation carriers to detect small amounts of tau early in the disease course. Although this remains speculative at this point, detecting small amounts of tau with a PET tracer like MK-6240 in subjects without symptoms could potentially enable identification of genetic FTLD mutation carriers who are close to disease onset.

Overall, our preliminary results align with MK-6240 binding predominantly to tau NFTs as previously established, and further support the tracer’s ability to potentially act as an effective in vivo diagnostic marker in forms of FTLD secondary to a MAPT mutation with NFT pathology. Importantly, this highlights to clinicians that a positive MK-6240 scan cannot be automatically equated to a diagnosis of Alzheimer's disease. Furthermore, while the sensitivity of MK-6240 as a molecular diagnostic marker remains to be further characterized, this study points towards it binding to tau with potentially higher specificity than previously-studied tau-PET tracers. Our findings in amyloid-negative P301L mutation carriers suggest that the potential of MK-6240 to act as a biomarker may even extend beyond the tauopathies which purely engender NFT pathology – although this requires further investigation. Finally, our approach of testing a biomarker exclusively in patients with genetic FTD in order to know the pathology a priori could potentially be of use for future studies.

An effective tau-PET tracer would likely contribute towards a better understanding of tau spreading in vivo while simultaneously transforming the current clinical approach to FTD. A reliable molecular diagnostic marker would constitute a crucial step towards eventually developing a treatment – in particular, by permitting selection of patients for trials of anti-tau therapies based on pathology, and by improving the ability to monitor treatment response and
disease progression. Ultimately, multiple tau-PET tracers may be required given the heterogeneity of tau pathology. However, in an area that sorely lacks in specific diagnostic tests at present, the results presented in this paper suggest MK-6240 could eventually be one of these biomarkers.

The main strength of this study is the recruitment of subjects with genetic FTD to be able to know in vivo which patients have tau pathology and which likely have TDP-43, thereby enabling us to confidently predict what results to expect from the MK-6240 scans. Furthermore, the size of the cohort (given the rarity of the disease) featuring diverse mutations is another asset. The major limitation is the lack of autopsy data to confirm results thus far. Even though the known mutations indicate the underlying pathology, the ambiguous nature of tau pathology renders it difficult to draw conclusions regarding whether the tracer is binding to anything other than NFTs – particularly in subjects with a P301L MAPT mutation. Finally, the presence of modest binding just above SUVR 1 must be interpreted with caution, as there can be confounding factors such as hypoperfusion or incomplete registration.

In conclusion, we observed the [18F]MK-6240 tau-PET tracer binding in vivo in subjects with symptomatic FTD secondary to a MAPT mutation, as well as modest binding in two presymptomatic MAPT carriers within five years of disease onset. Binding occurred predominantly in regions associated with tau pathology in FTLD, and was absent in the majority of subjects with symptomatic non-tau mutations. These results highlight that positive [18F]MK-6240 tau-PET does not necessarily imply a diagnosis of Alzheimer's disease, and point towards a potential use for [18F]MK-6240 as a biomarker in tauopathies beyond Alzheimer's disease, although further patient recruitment as well as autopsy studies will be necessary to determine clinical applicability.

**Figure legends**

**Figure 1: [18F]MK-6240 tau-PET scans in symptomatic MAPT mutation subjects**

A higher SUVR represents stronger binding. Binding to meninges, including the tentorium
cerebelli, is considered to be off-target. Scans are masked in order to minimize off-target binding
to meninges. (A) 71 year old man with bvFTD due to *P301L MAPT* mutation, FTLD-CDR 2,
MMSE 6/30. (B) 67 year old man with bvFTD due to *P301L MAPT* mutation, FTLD-CDR 2,
MMSE 8/30. (C) 60 year old woman with bvFTD due to *R406W MAPT* mutation, FTLD-CDR 1,
MMSE 29/30.

**Figure 2: [18F]MK-6240 tau-PET scans in presymptomatic MAPT mutation subjects**

A higher SUVR represents stronger binding. Binding to meninges, including the tentorium
cerebelli, is considered to be off-target. Scans are masked in order to minimize off-target binding
to meninges. (A) 30 year old man with asymptomatic *P301L MAPT* mutation, estimated years to
onset (EYO) 30, MMSE 29/30. (B) 57 year old woman with asymptomatic *P301L MAPT*
mutation, EYO 1, MMSE 29/30. (C) 52 year old man with asymptomatic *P301L MAPT*
mutation, EYO 5, MMSE 28/30.

**Figure 3: [18F]MK-6240 tau-PET scans in symptomatic non-tau mutation subjects**

A higher SUVR represents stronger binding. Binding to meninges, including the tentorium
cerebelli, is considered to be off-target. Scans are masked in order to minimize off-target binding
to meninges. (A) 51 year old man with bvFTD/svPPA due to *VCP* mutation, FTLD-CDR 0.5,
MMSE 23/25. (B) 41 year old man with bvFTD due to *C9orf72* mutation, FTLD-CDR 0.5,
MMSE 27/30. (C) 44 year old man with bvFTD due to C9orf72 mutation, FTLD-CDR 2, MMSE 12/30. (D) 61 year old man with bvFTD due to GRN mutation, FTLD-CDR 1, MMSE 19/30.

**Figure 4: FTD versus Cognitively Normal Model**

Results of the general linear model. Left: RFT-corrected maps showing voxels with the greatest difference between FTD and cognitively normal (CN), focusing on the slices showing salient voxels for inferior temporal cortex (top), basal ganglia (middle) and medial orbitofrontal cortex (bottom). Right: comparisons of SUVR distributions for the salient regions of interest (ROIs) including right inferior temporal cortex (top), left putamen (middle) and left medial orbitofrontal cortex (bottom). The significance is shown as follows: *p<0.05, **p<0.01 (two-sample t-test).

**Figure 5: Hippocampal Atrophy versus [18F]MK-6240 Temporal Meta-ROI SUVR**

Hippocampal atrophy and its association with MK-6240 SUVR in the temporal meta-ROI for the studied FTD cases. The T1-weighted MRI maps are shown both alone (top) and with MK-6240 SUVR overlaid (bottom) for (A) symptomatic MAPT, (B) non-tau mutation FTD, and (C) asymptomatic MAPT cases. (D) Adjusted hippocampal volume plotted versus MK-6240 SUVR in the temporal meta-ROI for each FTD case in this study. Note the three symptomatic MAPT cases having the lowest hippocampal volume and the highest MK-6240 SUVR among all cases.
