Abstract. The well-succeeded pregnancy in humans and rodents is the consequence of close interaction between maternal and fetal cells with intervening of cytokines and chemical mediators. In this process a pregnant uterus subset NK cells - uterine Natural Killer cells (uNK cells) play a pivotal modulatory role under the influence of local physiological hypoxia and other alterations. The aim of the present work was to evaluate the expression and commitment of induced form of nitric oxide synthase (iNOS) and NO concentration in the homeostasis of pregnant uterus. It was used normal pregnant mice on gd 10th and those submitted to surgical intervention to induce mechanical lesion in the embryos (SEE). Uterine samples were collected at 0.5, 1, 2 and 6 h after embryo lesion and processed for paraffin embedding and tissue homogenate. The samples destined for paraffin embedding was performed the Dolichos biflorus (DBA) lectin cytochemistry and anti-iNOS immunocytochemistry. The samples destined to tissue homogenates were processed for SDS-PAGE and Western-blot using anti-iNOS and evaluate of NO concentration. The embryo-injured uterine segments showed hyperemia and hemorrhage at mesometrial region in which the DBA lectin reaction showed altered uNK cells suggesting the degranulation. Positive reaction with anti-iNOS was seen on uNK cells, trophoblast giant cells, endometrial stromal and decidual cells and smooth muscle cells in the normal pregnant uterus, but 1 and 2 h after embryo lesion, the iNOS labeling decreased or was absent only in uNK cells. The same results was obtained with NO concentration. These results confirm the unique constitutive expression of iNOS in the pregnant mice uterus, being the uNK cells the only one responsive against stress of embryo failure, besides showing that excessive NO produced by quick activation of uNK-iNOS should affect the local vascular permeability.
Keywords: Natural killer cells; Nitric oxide; Nitric oxide synthase; Pregnancy mouse; iNOS and NO in the uterine maternal-fetal interface.

Introduction

The successful embryo implantation and development in human and rodents uterus is highly dependent of interaction and dialogue between maternal and fetal cells, with intervention of the cytokines and chemical compounds in fine balance (Dietl et al., 2006; Sojka et al., 2019). This dialogue involves the blood vessels, stromal cells and leukocytes in the endometrium from maternal side, and trophoblast cells from the embryo in a complex signaling network (Burton et al., 2009). Unbalance of these signals could result miscarriage (Dietl et al., 2006; Sojka et al., 2019). Intriguing was the participation of uterine natural killer cells (uNK) - a lymphocyte population that accumulates in the uterine environment specifically during pregnancy (Saito et al., 2000; Lima et al., 2014). In human, the CD56bright/CD16dim uNK cells can be distinguished from the CD56dim/CD16bright blood circulating NK (cNK) cells; the comparative microarray analyses showed several qualitative and quantitative differences on gene expression profile between these two NK cell subsets (Peng et al., 2010). In mice, the only way to distinguish uNK from cNK is the expression of Gal-N-Ac containing glycoconjuggestes on the surface of uNK reactive to Dolichos biflorus (DBA) lectin (Paffaro-Jr et al., 2003). These subpopulations differ functionally both in human and murine pregnant uterus. The cNK subset is more cytotoxic, has many cytolytic granules and express members of killer immunoglobulin-like receptor (KIR) family (Maynard et al., 2008; Leonard et al., 2013) while, the uNK cells in spite of high granule contents has low cytotoxicity, does not express KIRs, and experimentally it is mainly cytokine producing subset (Koopman et al., 2003).

Several unexplained recurrent pregnant loss in humans beings suggests immune based-etiology and proposed the participation of uNK cells (Croy et al., 2010; Cheng et al., 2012), but they have not experimentally proved yet. Therefore, to fully understand the involvement of uNK cells in the pregnancy, it is necessary to study these cells both in normal and abnormal situation of pregnancy. Using transgenic, knockout and mutant mice raised important contribution to understand the pathophysiological roles of uNK in pregnancy (Raulet et al., 2006); however most of them have systemic effects affecting a given pathway not specific to uNK cells in the pregnant uterus.

Recently, we developed an experimental model of surgical lesion performed in the embryo of pregnant mice to induce abnormal pregnancy status in the uterine environment (Lima et al., 2012). In this animal, the uNK cells seem to release their granules contents and induced hyperemia as soon as 30min after lesion that increased to focal hemorrhage after 1-2 h localized in the mesometrial region. This is the region where uNK cells migrate and accumulate in the pregnant mice uterus. These hyperemia and hemorrhage were also seen in the non-manipulated embryo implantation sites of same animal, suggesting a systemic effect of some soluble factor rather than driven by cytoltyc mediators like perforin, since the uNK did not seem to reach any target cell. Based on this evidence, it is plausible to suppose the involvement of nitric oxide (NO) - a potent vasoactive free radical which affects the vascular permeability (Gagioti et al., 2000; Murphy et al., 2005) and is an extremely unstable lipid-soluble gas and undergoes rapid oxidative degradation to the stable breakdown products nitrate and nitrite - and the inducible nitric oxide synthase (iNOS), the most effective catalytic enzyme to produce it; fact already described in mouse uNK cells (Hunt et al., 1997). Therefore, embryo failure could be closely related to changes on NO produced in the uterine environment, which affects the local homeostasis.
In the present work, there were adopted the surgical embryonic damage in pregnant mice to evaluate comparatively the iNOS expression in the maternal-fetal interface of abnormal and normal pregnant mouse uterine environment. And we quantified the presence of NO byproducts, nitrate and nitrite, because the NO is a short-life radical and this is used as markers for the release of NO.

Materials and methods

Animals
Female and male Swiss mice aging 10-12 weeks old were purchased from Animal Facilities (CEMIB) of University of Campinas and housed under 12 h light/12 h dark to mate with free access to water and food. The 1st gestational day (gd) was considered to be the first morning presenting the vaginal plug. All the animal handling agreed with Brazilian College of Animal Experimentation and was approved by Animal Bioethics and Experimentation of Institute of Biology, University of Campinas, Brazil (Proc. No. 1144-2).

Surgical Euthanasia of Embryo (SEE)
Pregnant mice on gd 10 were anesthetized with intraperitoneal injection of 5 mg/kg of xylazine chloride (Anasedan, Brazil) and 100 mg/kg of ketamine (Sespo, Brazil). After laparatomy, the uterine horns were exposed and a 15x5 gauge needle was introduced into the uterine wall through the antimesometrial side to damage the developing embryo. At least, two interspersed embryos were lesioned on the left uterine horn, while the right uterine horn was not manipulated. The muscle and skin incisions were sutured and after recovering from the anesthesia the animals were hold in individual cage. The control animals were handled in the same way, except for the mechanical embryo lesion, and sacrificed after 0.5, 1, 2 and 6 h of surgical procedure.

Cytochemistry and immunocytochemistry
At least, 3 animals from each experimental group of embryo lesioned or corresponding control animals were perfusion fixed with 30 mL of 4% paraformaldehyde (PFA) in 100 mM PBS pH 7.4 through the left ventricle. The uterine fragments containing embryo development sites were processed according to the conventional paraffin embedding and 5 μm thick paraffin sections were collected on silanized glass slides.

Dolichos biflorus (DBA) lectin cytochemistry was performed according to Paffaro Jr, et al. (2003). Briefly, desparaffinized sections were blocked with 1% bovine serum albumin (BSA type V, Sigma Chem. Co., St Louis, USA) in 100 mM PBS pH 7.4 and incubated with biotinylated DBA lectin (Sigma Chem. Co., St Louis, USA). After treatment with streptavidin-peroxidase (Chemicon, USA), the peroxidase was revealed with 0.5% diaminobenzidine (DAB) and hydrogen peroxide (H₂O₂).

There were employed, on paraffin sections, immunoperoxidase using the mouse monoclonal anti-iNOS diluted in the 0.5 μg/μL concentration (1:200) (Sigma Chem. Co., Louis, USA) as primary antibody and peroxidase conjugated rabbit anti-mouse (Santa Cruz, USA) as secondary antibody. After revelation with DAB and H₂O₂, the sections were counterstained with hematoxylin and mounted with synthetic Canada balsam under coverslips.

SDS-PAGE and Western-blot
The mesometrial lymphoid aggregate of pregnancy (MLAp) region was dissected from 2 embryo lesioned sites of 3 different animals of each experimental group. These tissue samples in ice cooled bath were homogenized in 10 mM Trizma base (Sigma Chem. Co., St Louis, USA) pH 7.4 containing 10 mM EDTA (Sigma Chem. Co., St Louis, USA), 10 mM sodium pyrophosphate (Sigma Chem. Co., St Louis, USA), 100 mM sodium fluoride (Sigma
Chem. Co., St Louis, USA), 10 mM sodium orthovanadate (Sigma Chem. Co., St Louis, USA), 2 mM PMSF (Sigma Chem. Co., St Louis, USA), 0.1 mg/mL aprotinin (Sigma Chem. Co., St Louis, USA) and 1% igepal (Sigma Chem. Co., St Louis, USA) using Glass-Col (USA) homogenizer. The homogenates were centrifuged (12,000g) for 30 min at 4 °C and the protein contents in the supernatants were evaluated according to Bradford et al. (1976).

The SDS-polyacrylamide gel electrophoresis were performed with 30 μg proteins from each samples and Prestained SDS-PAGE Standards High Range (Bio Rad) as molecular weight marker in 7.5 slab gels (8.5 x 7.3 cm) prepared according to Laemmli et al. (1970) using Mini Protean III system and Power Pac 300 (Bio Rad, USA) as power source. After electrophoresis, the proteins were blotted to the membrane (Immobilon–P-Transfer Membrane, Millipore, USA). The membranes were washed in 100 mM Tris-buffer 50 mM with 0.5% Tween 20 (TBS-T) followed by blocking with 5% defatted milk (Molico, Nestle, Brazil) in TBS-T and incubation with mouse monoclonal anti-iNOS (1:1000) overnight at 4 °C. There were used peroxidase-conjugated rabbit anti-mouse polyclonal antibody for anti-iNOS and Luminol Kit (SuperSignal WestPico–Chemiluminescent Substrate, Pierce, USA); the membranes were scanned for densitometry. The luminescence were quantified as pixels density using UN-SCAN-IT-5.1 (Silk Scientific Corp., Orem, UT) and the statistical significance (P < 0.05) were evaluated with ANOVA.

Nitrate and nitrite assay (NO)
The sample of MLAp region were collected was performed according to the item 2.5 and was additionally centrifuged with centricon (Amicon, Inc, USA) during 30 min, 12,000 g at 4 °C and storage to -70 °C until the moment of use. The sample was diluted 1:10 in 100 mM PBS pH 7.4 to determine the amount of nitrate and nitrite by colorimetric test (Cayman Chemical, USA) and the reading was made in reader of ELISA (Molecular Devices, California 94089) and the analyses was made in program SoftmaxPro between 540 and 550 nm. The sample was compared with standard curve of nitrate and nitrite. The statistics analyses of averages ±SD and the degree of significance were made by ANOVA test.

Results
The uterus submitted to surgical euthanized of the embryos have shown hyperemia on the mesometrial side under macroscopic evaluation 1, 2 and 6 h after lesion and showed increase to localized hemorrhage. Those embryo developing sites surrounded the lesioned ones have shown the same hyperemic or hemorrhage reaction and the non-manipulated right horn also showed the hyperemic reaction.

In the mesometrial half of each embryo developing sites in the normal pregnant uteri of gd 10 were distributed the DBA lectin positive uNK cells, with dominance of subtypes III and IV in the decidualized endometrium nearest the embryo and the subtypes I and II in the non-decidualized endometrium and myometrium. The uNK cells - in the uteri submitted to embryo damage changed the reaction pattern with DBA lectin; being noticeable the formation of large cytoplasmic vacuoles and loss of granules contents reactivity in the uNK subtypes III and IV since 1 h after lesion. After 6 h, the uNK subtypes II also showed loss of reactivity in the granules.

The anti-iNOS immunocytochemistry performed in the normal pregnant uterus showed strong reaction in the cytoplasm of uNK cells (Figure 1a) and trophoblast giant cells (Figure 1b), and weak reaction in endometrial stromal cells and smooth muscle cells of myometrium (Figure 1c). In the embryo-lesioned samples, the reaction intensity did not change in trophoblast cells or in the endometrial stromal or myometrial cells. In the uNK cells, the reactions became weaker after 1 and 2 h (Figure 1d), if compared to those of...
normal pregnancy; and after 6 h, the reactivity was restored in the most of uNK cells (Figure 1e).

**Figure 1.** Photomicrographs of anti-iNOS immunoperoxidase reaction in pregnant mouse uterus on 10th dg, counterstained with hematoxylin. A and B) anti-iNOS positive reaction in the cytoplasm of uNK cells (arrows) and trophoblast giant cells (white arrows) in the uterus of normal pregnancy, respectively. (*) blood vessels, (#) antimesometrial decidual cells; C) anti-iNOS positive reactions in the smooth muscle cells (arrows) of myometrium; D) weak or absence of anti-iNOS reaction on most of uNK cells (arrows) after 2 h of embryo lesion. Note the blood cells retained in the enlarged blood vessels (*) even after vascular perfusion with fixative solution; E) uNK cells showing anti-iNOS positive reaction partially recovered beside other negatives (arrows) after 6 h of embryo lesion; Bars = 30 μm.

The same data was confirmed by *Western blot* and revealed a 130 kDa single band reactive to anti-iNOS in all samples evaluated (Figure 2a). The densitometry analysis of the bands showed significant (p < 0.05) decreased in the intensity at 1 and 2 h after embryo lesion compared to normal pregnancy and restoring on the intensity after 6 h. The quantified of nitrate and nitrite showed a high proportion of free radicals in the form of nitrate and a low production in the form of nitrite and was observed peak of production after 0.5 h of SEE, reduce of production in 2 h and return of production in 6 h (Figure 2b).
Figure 2. A)- Western-blot of iNOS revealed by chemoluminescence after SDS-PAGE of uterine homogenates from normal pregnancy (N), 1, 2, 6 h after embryo lesion and 6 h after LPS treatment. B)- histogram of the corresponding densitometry values showed significant low values (p < 0.05) at 1 and 2 h after lesion when compared to normal pregnant uterus.

Figure 3. Nitrate and nitrite concentration in the uterus after SEE.

The quantification of nitrate and nitrite showed decreased in the production of NO after 0.5 h and completely loss in 2 h after SEE (Figure 3).

Discussion

The mechanism concerning the complex dialogue established between the cells of maternal-fetal interface in the pregnant uterus is still not completely understood, therefore, the need of assurance regarding the clinical intervention in the abnormal pregnancy or recurrent abortions. Development of experimental model of abnormal
pregnancy to study changes in the maternal-fetal interface should be helpful to understanding the fine mechanism controlling the homeostasis of pregnant uterus.

Previously, we used the surgical intervention to induce embryo damage in pregnant mice and reported the changes on morphology and function of uNK cells committed to cytotoxic activity - in response to abnormal status of uterine environment (Lima et al., 2017). Also, was identified that SEE activated the regulated secretory pathway of DBA(+) uNK cells in vivo, mobilizing perforin and granymes, but not Vegfa (Lima et al., 2014). The hyperemia and hemorrhage seen in the mesometrial side of the uterus were supposed to be the consequences of the embryo lesion involving the uNK cells.

Actually, the embryo lesion performed in the pregnant mice on gd 10 used in the present work showed a localized hyperemic reaction, as soon as 1 h after lesion, which evolved to hemorrhage after 2 h, confirming the alteration on vascular permeability and/or disruption of vascular wall in the blood vessels of mesometrial side of the uterus. No noticeable damage on artery walls was observed under histological evaluation, suggesting the integrities of small venous type and capillaries vessels were mainly affected.

The DBA lectin cytochemistry is the most selective method to identify the uNK cells (Bulmer et al., 2019) in the pregnant mouse uterus. All the embryo-lesioned uteri samples showed changes in the pattern of DBA lectin reactivity of uNK cells with looseness of labeling in the granules contents, as was previously reported (Lima et al., 2017). The granules of uNK cells contain cytolytic proteins like perforin and granzymes (Baltayeva et al., 2019) and their degranulation and release of these mediators suggests activation of innate immune response. This is a unique pathophysiological response of uNK cells since it has longer been considered a non-killing NK cell in pregnant uterus (Raulet et al., 2006).

The expression of induced isoform of nitric oxide synthase (iNOS) in the pregnant uterus was already reported (Bulmer et al., 2019), beside our immunocytochemical, which data show its expression in trophoblast giant cell, endometrial stromal cells, uNK cells and myometrium smooth muscles. It confirms the pregnant uterine environment normally induces the expression of this NOS isoform to produce nitric oxide (NO) in the maternal-fetal interface. NO is a short-lived free radical and intercellular messenger that mediates a variety of biological functions, including vascular homeostasis as vasodiating agents by relaxing arterial and venous smooth muscles (Madamanchi et al., 2005). The dg 10 is the period of intensive endometrial remodeling with angiogenesis required for the organogenesis of the placenta in pregnant mouse uterus; and this process of neovascularization results from hypoxia and induction of various angiogenic factors – the basic conditions that are necessary to support embryo development in the endometrial of animals of hemochorial type placentation.

Among the cells in the uterus showing iNOS expression, the uNK cells should play a crucial role in the angiogenesis due to their localization at mesometrial side closely associated to the spiral arteries and interposing the maternal interface to the growing placenta. Therefore, hyperemia and hemorrhage in this area after embryo lesion seems to be consequence of imbalance of NO produced in high level by uNK cells. On the other hand, the oxidative stress, which is defined as toxicity inflicted by reactive oxygen species (ROS) and reactive nitrogen species (RNS), including NO is assumed to contribute to the state of immunosuppression by inhibiting the function of NK cells and other lymphocytes, being interesting that IL-2 and other NK-cell-activating cytokines are ineffective in an environment of oxidative stress (Baltayeva et al., 2019). Therefore, the NO produced by uNK cells could be an autocrine or intracrine-like action to down-regulate the cytotoxic activity of these cells in the normal pregnant uterus.

It was intriguing the decreasing on reactivity of iNOS detected by immunolabeling only in uNK cells of the uteri after 1 and 2 h embryo lesion. It suggests different mechanisms modulating the iNOS expression and activation of the cells in maternal-fetal
interface. The bypass of iNOS-NO production in up-regulated oxidative stress status of living tissues like in burn-trauma occurs in first hour after trauma (Horton et al., 2003). In the case of uNK cells, they synthesize iNOS “constitutively” under normal pregnancy and it is available for quick mobilization to catalyze the NO production.

According to Haddad et al (1995) the production of nitrate is more sensible than production of nitrite and this used to determine the amount total of NO present in the half after the diverse treatments.

However, it is reasonable to suppose the response of uNK cells under embryo trauma increasing the demand of local oxygenation to increase the production of NO by fast consumption of iNOS. This was detected as reduced or absence of immunolabeling in the 1 and 2 h after embryo lesion. The peak of iNOS production in resting cells is usually observed after 0.5 h of embryo lesion, but since the iNOS is “constitutively” produced by many cells in the pregnant uterus their NO production could be catalyzed faster than any other place. Therefore, the imbalanced high production of NO - by activating the iNOS enzyme available in the uNK cells, which are located at the mesometrial half of the embryo developing site - should be determinant of increased vascular permeability resulting in hyperemia and hemorrhage seen in this uterine region. In fact, the Western-blot analysis confirmed the lowering of iNOS expression at 1 and 2 h after embryo lesion if compared to normal animals, which should be the relative amount of iNOS disposed by uNK cells in the pregnant uterus and the remainder level belonging to the other iNOS positive cells, which are not affected by or responsive to embryo lesion.

In fact, the immunocytochemistry showed changes on iNOS only in the uNK cells. However, since in the uterus many cells, including the uNK, showed constitutive expression during pregnancy, it must be revised in the future by additional experiment focusing the uNK cells to evaluate them at shorter and longer time rather the conventional 6 h used in other organs and tissues.

It was the unequivocal involvement of uNK cells and iNOS in the abnormal status of pregnancy induced by two different models of embryo failure used in the present work and therefore, evaluations of the iNOS and NO levels could be helpful as additional parameter to early evaluation for clinical diagnosis in many cases of pregnancy failure.
