Missed retained knife blade injury: A potentially lethal trap for the unwary

ABSTRACT

Introduction: Retained knife blade is an uncommon injury and they often present in a spectacular fashion. Concealed retained knife blade, however, is difficult to diagnose without a detailed clinical and radiological assessment. Extraction requires careful planning in a controlled environment, preferably in the operating theater. Case Report: We present the highly unusual case of a 25-year-old male in whom a retained knife blade following a stab to the left anterior leg was missed on three separate visits to a rural hospital. Conclusion: Whilst diagnosis and management continues to be challenging, clinicians must always remain vigilant to the possibility of such injury. When the presentation is unclear, a high level of suspicion, careful clinical assessment and judicious use of radiography is of paramount importance. Early referral to a trauma center for definitive management is crucial.

INTRODUCTION

Knife injuries are common and can present with a full spectrum of pathology, ranging from minor cuts to severe life-threatening injuries. Retained knife blade injury logically falls within the scope of this injury spectrum [1]. Delayed presentation due to missed injuries is associated with significant morbidity [2]. We report a highly unusual case of a 25-year-old male who presented to our trauma unit some three weeks after the initial injury, with a concealed, retained knife blade in the left leg. It emerged that the actual injury was missed and he had been sent home by the doctor on multiple occasions.

CASE REPORT

Mr. B was 25-year-old male who presented to a rural hospital following a single stab injury to the left anterior leg. He was moderately intoxicated at the time. He was assessed by a locum doctor at the hospital and was thought to be an uncomplicated superficial stab wound.
He was discharged home after being given a prescription for paracetamol. One week after his initial injury, the patient presented again complaining of increasing pain from the wound. Apart from some localized tenderness, there was no discharge or surrounding cellulitis. He was given a course of oral flucloxacillin, 250 mg, four times daily for presumable wound sepsis. He represented again the following week with no improvement and complained of a sense of fullness and increasing pain in the anterior leg extending to the calf. It was decided that antibiotics dose was to be increased and he was again discharged with a further course of oral flucloxacillin, this time at 500 mg, four times daily. A week later, he presented for the third time complaining of worsening of his symptoms, and at the patient’s insistence, he was referred to our trauma unit for a second opinion.

On arrival, the patient was in significant discomfort. His baseline vitals were: heart rate: 90/min, blood pressure: 135/70 mmHg, temperature 37.5°C. A small puncture wound (approximately 1.5x1.5 cm) was noted in the anterior aspect of the left leg (Figures 1 and 2) and approximately 10 cm inferior to the tibial tuberosity. The wound edges appear sloughy, with no surrounding cellulitis. Tenderness was noted that extended from anterior leg to the calf but no foreign body was palpable. His pulses in the lower limbs were normal and equal, with normal Doppler flow signal. Suspicion was aroused about the retention of a foreign body and an urgent X-ray was arranged. A large retained knife blade was seen, with the trajectory in the superior direction, lodged between the interosseus membrane (Figure 3). He was commenced on intravenous co-amoxiclav, 1.2 g, and was taken immediately to the operating theatre for a planned removal. Intraoperatively, a longitudinal incision was made extending from the wound edge, and the knife blade was immediately visible. The knife blade was easily extracted with minimal hemorrhage (Figure 4). There was no evidence of osteomyelitis. An on-table angiography was performed, which showed no vessel injuries. The wound was thoroughly irrigated and was left to close by secondary intention. He had an uneventful recovery and was discharged on fifth day.

**Figure 1:** Stab wound on the anterior aspect of the left tibia, seen 3 weeks after the initial injury.

**Figure 2:** Approximate dimension of the wound, note the sloughy edge.

**Figure 3:** X-ray depicting the retained knife blade. Note the direction of the blade.

**DISCUSSION**

Retained knife blade remains a rather uncommon injury [1]. Most of these injuries usually present in spectacular fashion and the protruding objects are usually obviously visible [3, 4]. Heroic attempts at extraction in the emergency department may result in massive torrential hemorrhage [5]. Most experience reported in literatures has been from isolated case reports and several small case series [1, 6, 7]. Being an uncommon injury, most centers have limited experience in its management [1]. Concealed retained knife blade injury is much more
Once the retained knife blade was identified, the issue with definitive management can be difficult. In most situations, a spiral computed tomography (CT) scan can usually help defining the relation between the retained blade and major significant anatomical structures [5]. This will generally facilitate a far safer extraction plan [1]. Angiography is generally recommended if initial CT scan is equivocal, especially if a major vascular injury is suspected [1]. In our case, we elected to pursue a combined exploration and extraction in the operating theater due to the anatomical location of the injury. It was anticipated that major hemorrhage in the vessels inferior to the arterial trifurcation of the knee could be safely dealt with and adequate vascular control achieved. Furthermore, if there were injuries to one of the small branches from the trifurcation, it was highly unlikely this would have significant impact on the lower limb perfusion, and a simple ligation would have been a safe option [9]. The subsequent on table angiogram performed proved to be reassuring. Despite the patient’s protracted delayed to missed diagnosis on multiple occasions, he fortunately made a full recovery.

**CONCLUSION**

Retained knife blade is an uncommon injury. Concealed, retained knife blade is notoriously to diagnose. Therefore, a high index of suspicion must be maintained, coupled with judicious use of imagining, especially if the history is unclear. Early and carefully planned extraction in the operating theatre by a suitably trained trauma specialist remains the cornerstone of good management.
