Abstract

Previous analytical studies of on-line Independent Component Analysis (ICA) learning rules have focussed on asymptotic stability and efficiency. In practice the transient stages of learning will often be more significant in determining the success of an algorithm. This is demonstrated here with an analysis of a Hebbian ICA algorithm which can find a small number of non-Gaussian components given data composed of a linear mixture of independent source signals. An idealised data model is considered in which the sources comprise a number of non-Gaussian and Gaussian sources and a solution to the dynamics is obtained in the limit where the number of Gaussian sources is infinite. Previous stability results are confirmed by expanding around optimal fixed points, where a closed form solution to the learning dynamics is obtained. However, stochastic effects are shown to stabilise otherwise unstable sub-optimal fixed points. Conditions required to destabilise one such fixed point are obtained for the case of a single non-Gaussian component, indicating that the initial learning rate $\eta$ required to successfully escape is very low ($\eta = O(N^{-2})$ where $N$ is the data dimension) resulting in very slow learning typically requiring $O(N^3)$ iterations. Simulations confirm that this picture holds for a finite system.
1 Introduction

Independent component analysis (ICA) is a statistical modelling technique which has attracted a significant amount of research interest in recent years (for a review, see Hyvärinen, 1999). In ICA the goal is to find a representation of data in terms of a combination of statistically independent variables. This technique has a number of useful applications, most notably blind source separation, feature extraction and blind deconvolution. A large number of neural learning algorithms have been applied to this problem, as detailed in the aforementioned review.

Theoretical studies of on-line ICA algorithms have mainly focussed on asymptotic stability and efficiency, using the established results of stochastic approximation theory. However, in practice the transient stages of learning will often be more significant in determining the success of an algorithm. In this paper a Hebbian ICA algorithm is analysed and a solution to the learning dynamics is obtained in the limit of large data dimension. The analysis highlights the critical importance of the transient dynamics and in particular an extremely low initial learning rate is found to be essential in order to avoid trapping in a sub-optimal fixed point close to the initial conditions of the learning dynamics.

This work focuses on the bigradient learning algorithm introduced by Wang and Karhunen (1996) and studied in the context of ICA by Hyvärinen and Oja (1998) where it was shown to have nice stability conditions. This algorithm can be used to extract a small number of independent components from data of high dimension and is closely related to projection pursuit algorithms which detect “interesting” projections in high-dimensional data. The algorithm can be defined in on-line mode or can form the basis of a fixed-point batch algorithm which has been found to improve computational efficiency (Hyvärinen and Oja, 1997). In this work the dynamics of the on-line algorithm is studied. This may be the preferred mode when the model parameters are non-stationary or when the data set is very large. Although the analysis is restricted to a stationary data model, the results are relevant to the non-stationary case in which learning strategies are often designed to increase the learning rate when far from the optimum (Müller et al., 1998). The results obtained here suggest that this strategy can lead to very poor performance.

In order to gain insight into the learning dynamics an idealised model is considered in which data is composed of a small number of non-Gaussian source signals linearly mixed in with a large number of Gaussian signals. A solution to the dynamics is obtained in the limiting case where the number of Gaussian signals is infinite. In this limit one can use techniques from statistical mechanics similar to those which have previously been applied to other on-line learning algorithms, including other unsupervised Hebbian learning algorithms such as Sanger’s PCA algorithm (Biehl and Schlösser, 1998). For the asymptotic dynamics close to an
optimal solution the stability conditions due to Hyvärinen and Oja (1998) are confirmed and the eigensystem is obtained which determines the asymptotic dynamics and optimal learning rate decay. However, the dynamical equations also have sub-optimal fixed points which are stable for any $O(N^{-1})$ learning rate where $N$ is the data dimension. Conditions required to destabilise one such fixed point are obtained in the case of a single non-Gaussian source, indicating that learning must be very slow initially in order to learn successfully. The analysis requires a careful treatment of fluctuations which prove to be important even in the limit of large input dimension. Finally, simulation results are presented which indicate that this phenomenon persists also in finite sized systems.

2 Data model

The linear data model is shown in figure 1. In order to apply the Hebbian ICA algorithm one should first sphere the data, i.e. linearly transform the data so that it has an identity covariance matrix. This can be achieved by standard transformations in a batch setting but for on-line learning an adaptive sphering algorithm, such as the one introduced by Cardoso and Laheld (1996), could be used. To simplify matters it is assumed here that the data has already been sphered. Without loss of generality it can also be assumed that the sources each have unit variance. The sources are decomposed into $M$ non-Gaussian and $N - M$ Gaussian components respectively,

$$p(s) = \prod_{i=1}^{M} p_i(s_i), \quad p(n) = \prod_{i=M+1}^{N} \frac{e^{-n_i^2/2\sigma^2}}{\sqrt{2\pi}}.$$  \hspace{1cm} (1)

To conform with the above model assumptions the mixing matrix $A$ must be unitary. The mixing matrix is decomposed into two rectangular matrices $A_s$ and $A_n$ associated with the non-Gaussian and Gaussian components respectively,

$$x = A \begin{bmatrix} s \\ n \end{bmatrix} = [A_s \ A_n] \begin{bmatrix} s \\ n \end{bmatrix} = A_s s + A_n n.$$  \hspace{1cm} (2)

The unitary nature of $A$ results in the following constraints,

$$[A_s \ A_n] \begin{bmatrix} A_s^T \\ A_n^T \end{bmatrix} = A_s A_s^T + A_n A_n^T = I,$$  \hspace{1cm} (3)

$$\begin{bmatrix} A_s^T \\ A_n^T \end{bmatrix} [A_s \ A_n] = \begin{bmatrix} A_s^T A_n \ A_s^T A_n \\ A_n^T A_s \ A_n^T A_n \end{bmatrix} = \begin{bmatrix} I & 0 \\ 0 & I \end{bmatrix}.$$  \hspace{1cm} (4)
The linear mixing model generating the data is shown above. There are $M$ non-Gaussian independent sources $s$ while the remaining $N - M$ sources $n$ are uncorrelated Gaussian variables. There are $N$ outputs $x$ formed by multiplying the sources by the square non-singular mixing matrix $A \equiv [A_s\ A_n]$. The outputs are linearly projected onto the $K$-dimensional vector $y = W^T x$. It is assumed that $M \ll N$ and $K \ll N$.

3 Algorithm

The following on-line Hebbian learning rule was introduced by Wang and Karhunen (1996) and analysed in the context of ICA by Hyvärinen and Oja (1998),

$$W^{t+1} - W^t = \eta \sigma x^t \phi(y^t)^T + \alpha W^t (I - (W^t)^T W^t),$$

where $\phi(y^t)_i = \phi(y^t_i)$ is an odd non-linear function which is applied to every component of the $K$-dimensional vector $y \equiv W^T x$. The first term on the right is derived by maximising the non-Gaussianity of the projections in each component of the vector $y$. The second term ensures that the columns of $W$ are close to orthogonal so that the projections are uncorrelated and of unit variance. The learning rate $\eta$ is a positive scalar parameter which must be chosen with care and may depend on time. The parameter $\alpha$ is less critical and setting $\alpha = 0.5$ seems to provide reasonable performance in general. The diagonal matrix $\sigma$ has elements $\sigma_{ii} \in \{-1, 1\}$ which ensure the stability of the desired fixed point. The elements of this matrix can either be chosen adaptively or can be chosen according to á priori knowledge about the source statistics. Stability of the optimal fixed point is

Figure 1: The linear mixing model generating the data is shown above.
ensured by the condition (Hyvärinen and Oja, 1998),

$$\sigma_{ii} = \text{Sign}(\langle s_i \phi(s_i) - \phi'(s_i) \rangle) ,$$

assuming we order indices such that $y_i \to \pm s_i$ for $i \leq \min(K, M)$ asymptotically. The angled brackets denote an average over the source distribution.

A remarkable feature of the above algorithm is that the same non-linearity can be used for source signals with very different characteristics. For example, both sub-Gaussian and super-Gaussian signals can be separated using either $\phi(y) = y^3$ or $\phi(y) = \tanh(y)$, two common choices of non-linearity.

### 4 Dynamics for large input dimension

Define the following two matrices,

$$R \equiv W^T A_s , \quad Q \equiv W^T W .$$

Using the constraint in equation (3), one can show that,

$$y = W^T (A_s s + A_i n) = Rs + z \quad \text{where} \quad z \sim \mathcal{N}(0, Q - RR^T) .$$

Knowledge of the matrices $R$ and $Q$ is therefore sufficient to describe the relationships between the projections $y$ and the sources $s$ in full. Although the dimension of the data is $N$, the dimension of these matrices is $K \times M$ and $K \times K$ respectively. The system can therefore be described by a small number of macroscopic quantities in the limit of large $N$ as long as $K$ and $M$ remain manageable.

In appendix A it is shown that in the limit $N \to \infty$, $Q \to I$ while $R$ evolves deterministically according to the following first order differential equation,

$$\frac{dR}{d\tau} = \mu \sigma \left( \langle \phi(y)s^T \rangle - \frac{1}{2} \langle \phi(y)y^T + y\phi(y)^T \rangle R \right) - \frac{1}{2} \mu^2 \langle \phi(y)\phi(y)^T \rangle R \quad (9)$$

with rescaled variables $\tau \equiv t/N$ and $\mu \equiv N \eta$. This deterministic equation is only valid for $R = O(1)$ and a different scaling is considered in section 4.2 in which case fluctuations have to be considered even in the limit. The brackets denote expectations with respect to the source distribution and $z \sim \mathcal{N}(0, I - RR^T)$. The bracketed terms therefore only depend on $R$ and statistics of the source distributions, so that the above equation forms a closed system.
4.1 Optimal asymptotics

The desired solution is one where as many as possible of the \( K \) projections mirror one of the \( M \) sources. If \( K < M \) then not all the sources can be learned and which ones are learned depends on details of the initial conditions. If \( K \geq M \) then which projections mirror each source also depends on the initial conditions. For \( K > M \) there will be projections which do not mirror any sources; these will be statistically independent of the sources and have a Gaussian distribution with identity covariance matrix.

Consider the case where \( y_i \to s_i \) for \( i = 1 \ldots \min(K, M) \) asymptotically (all other solutions can be obtained by a trivial permutation of indices and/or changes in sign). The optimal solution is then given by \( R_{ij}^* = \delta_{ij} \) which is a fixed point of equation (9) as \( \mu \to 0 \). Asymptotically the learning rate should be annealed in order to approach this fixed point and the usual inverse law annealing can be shown to be optimal subject to a good choice of prefactor,

\[
\mu \sim \frac{\mu_0}{\tau} \quad \text{as} \quad \tau \to \infty \quad \left( \text{or equivalently} \quad \eta \sim \frac{\mu_0}{t} \quad \text{as} \quad t \to \infty \right).
\]  

(10)

The asymptotic solution to equation (9) with the above annealing schedule was given by Leen et al. (1998). Let \( u_{ij} = R_{ij} - R_{ij}^* \) be the deviation from the fixed point. Expanding equation (9) around the fixed point one obtains,

\[
u_{ij}(\tau) \sim \sum_{k,n=1}^{K} \sum_{l,m=1}^{M} V_{ijkl} \left\{ -\frac{1}{2} X_{kl}(\phi'(s_n)) \delta_{nm} + \left( \frac{\tau_0}{\tau} \right) - \mu_0 \lambda_{kl} u_{nm}(\tau_0) \right\} V_{kl}^{-1} \delta_{nm},
\]  

(11)

where,

\[
X_{ij} = \left( \frac{\mu_0^2}{-\mu_0 \lambda_{ij} - 1} \right) \left[ \frac{1}{\tau} - \frac{1}{\tau_0} \left( \frac{\tau_0}{\tau} \right) - \mu_0 \lambda_{ij} \right].
\]  

(12)

Here, \( \tau_0 \) is the time at which annealing begins and \( \lambda_{ij} \) and \( V_{ijkl} \) are the eigenvalues and eigenvectors of the Jacobian of the learning equation to first order in \( \mu \). These are written as matrices and tensors respectively rather than scalars and vectors because the system’s variables are in a matrix. One can think of pairs of indices \( (i, j) \) and \((k, l)\) as each representing a single index in a vectorised system. The explicit solution to the eigensystem is given in appendix B. From the eigenvalues, defined in equation (28), it is clear that the fixed point is stable if and only if the condition in equation (10) is met.

There is a critical learning rate, \( \mu_0^{\text{crit}} = -1/\lambda_{\text{max}} \), where \( \lambda_{\text{max}} \) is the largest eigenvalue (smallest in magnitude, since the eigenvalues are negative), such that if \( \mu_0 < \mu_0^{\text{crit}} \) then the approach to the fixed point will be slower than the optimal \( 1/\tau \) decay. From the eigenvalues given in (28) we find that \( \lambda_{\text{max}} = -\xi_{\text{min}} \) where
\[ \xi_i = \sigma_{ii} \langle s_i \phi(s_i) - \phi'(s_i) \rangle, \]  
so that \[ \mu_0^{\text{crit}} = 1/\xi_{\min}. \]  
As long as \( \mu_0 > \mu_0^{\text{crit}} \) then the terms involving \( \tau_0 \) in equations (11) and (12) will be negligible and the asymptotic decay will be independent of the initial conditions and transient dynamics.

Assuming \( \mu_0 > \mu_0^{\text{crit}} \) and substituting in the explicit expressions for the eigen-system we find the following simple form for the asymptotic dynamics to leading order in \( 1/\tau \),

\[ u_{ij}(\tau) \sim -\delta_{ij} \left( \frac{\mu_0^2 \langle \phi^2(s_i) \rangle}{4\mu_0 \xi_i - 2} \right). \tag{13} \]

### 4.2 Escape from the initial transient

Unfortunately, the optimal fixed points described in the previous section are not the only stable fixed points of equation (9). In some cases the algorithm will converge to a sub-optimal solution in which one or more potentially detected signals remain unlearned and the corresponding entry in \( R \) decays to zero. The stability of these points is due to the \( O(\mu^2) \) term in equation (12) which becomes less significant as the learning rate is reduced, in which case the corresponding negative eigenvalue of the Jacobian eventually vanishes. Higher order terms then lead to instability and escape from this sub-optimal fixed point. One can therefore avoid trapping by selecting a sufficiently low learning rate during the initial transient.

Consider the simplest case where \( K = M = 1 \) in which case the matrix \( R \) reduces to a scalar: \( R = R_{11} \) and \( \sigma = \sigma_{11} \). Expanding equation (12) around \( R = 0 \),

\[ \frac{dR}{d\tau} = -\frac{1}{2} \langle \phi(z)^2 \rangle \mu^2 R + \frac{1}{6} \kappa_4 \langle \phi'''(z) \rangle \sigma R^3 + O(R^5). \tag{14} \]

Here, \( \kappa_4 \) is the fourth cumulant of the source distribution and the brackets denote averages over \( z \sim N(0, 1) \). Although \( R = 0 \) is a stable fixed point, the range of attraction is reduced as \( \mu \to 0 \) until eventually instability occurs. The condition under which one will successfully escape the fixed point is found by setting \( d|R|/dt > 0 \),

\[ \sigma = \text{Sign}(\kappa_4 \langle \phi'''(z) \rangle), \quad \mu < \frac{\langle \phi''(z) \rangle \kappa_4}{3 \langle \phi^2(z) \rangle}. \tag{15} \]

Notice that the condition on \( \sigma \) for escaping the initial transient is not generally the same as the condition in equation (14) which ensures stability of the asymptotic fixed point. For \( \phi(y) = y^3 \) the conditions are exactly equivalent. However, in other cases the conditions may conflict and an adaptive choice of \( \sigma \) based on equation (15), as suggested by Hyvärinen and Oja (1998), may give poor results. With \( \phi(y) = \tanh(y) \) the conditions appear to be equivalent in many cases. This condition is
equally applicable to gradient based batch algorithms since it is due to the $O(\mu)$ term above, which is not related to fluctuations.

If the entries in $A$ and $W$ are initially of similar order then one would expect $R = O(N^{-\frac{1}{2}})$. This is the typical case if we consider a random and uncorrelated choice for $A$ and the initial entries in $W$. Larger initial values of $R$ could only be obtained with some prior knowledge of the mixing matrix which we will not assume. With $R = O(N^{-\frac{1}{2}})$ the initial value of $\mu$ required to escape is $O(N^{-1})$, indicating a very slow initial phase in the dynamics (recall that the unscaled learning rate $\eta \equiv \mu/N$). Larger learning rates will result in trapping in the sub-optimal fixed point. However, the above result is not strictly valid unless $R = O(1)$, since this was an assumption used in the derivation of equation (9). When $R = O(N^{-\frac{1}{2}})$ then one can no longer assume that fluctuations are negligible as $N \to \infty$. Define the $O(1)$ quantities $r \equiv R\sqrt{N}$ and $\nu \equiv \eta N^2$. The mean and variance of the change in $r$ at each learning step can be calculated (to leading order in $N^{-1}$),

$$E[\Delta r] \simeq \left( \frac{1}{2}(\phi^2(z))\nu^2 r + \frac{1}{6}\kappa_4(\phi'''(z))\sigma\nu r^3 \right) N^{-3},$$  \hspace{1cm} (16)

$$\text{Var}[\Delta r] \simeq (\phi^2(z))\nu^2 N^{-3}. \hspace{1cm} (17)$$

This expression is derived by a similar adiabatic elimination of $Q_{11}$ as carried out for the deterministic case in appendix A. This requires that $\alpha$ and $\eta$ are the same order before taking the limit $N \to \infty$, followed by the limit $\alpha \to \infty$ and corresponds to the usual form of “slaving” in Haken’s terminology in which the eliminated variable only contributes to the change in mean. Other scalings may result in slightly different expressions (see, for example, Gardiner, 1985, section 6.6) although it is expected that the main conclusions described below will not be affected.

The equation for the mean is similar to equation (14). However, the variance is the same order as the mean in the limit $N \to \infty$ and fluctuations cannot be ignored in this case. The system is better described by a Fokker-Planck equation (see, for example, Gardiner, 1985) with a characteristic time-scale of $O(N^3)$. The system is locally equivalent to a diffusion in the following quartic potential,

$$U(r) = \frac{1}{4}(\phi^2(z))\nu^2 r - \frac{1}{24}\kappa_4(\phi'''(z))\nu r^4,$$ \hspace{1cm} (18)

with a diffusion coefficient $D = (\phi^2(z))\nu^2$ which is independent of $r$. The shape of this potential is shown in figure 2. A potential barrier $\Delta U$ must be overcome to escape an unstable state close to $R = 0$ (assuming that the condition on $\sigma$ in equation (15) is satisfied).

For large $\nu$ this system corresponds to an Ornstein-Uhlenbeck process with a Gaussian stationary distribution of fixed unit variance. Thus, if one chooses too
Figure 2: For \( r = R\sqrt{N} = O(1) \) the dynamics can be represented as a diffusion in a symmetric quartic potential \( U(r) \). The escape time from an unstable fixed point at \( r = 0 \) is mainly determined by the potential barrier \( \Delta U \).

large \( \nu \) initially the dynamics will become localised close to \( R = 0 \). As \( \nu \) is reduced the potential barrier confining the dynamics is reduced. The time-scale for escape for large \( \nu \) is mainly determined by the effective size of the barrier (Gardiner, 1985),

\[
T_{\text{escape}} \propto \exp \left( \frac{\Delta U}{D} \right) = \exp \left( \frac{3\langle \phi^2(z) \rangle \nu}{8|\kappa_4\langle \phi'''(z) \rangle|} \right).
\]

As the learning rate is reduced so the time-scale for escape is also reduced. However, the choice of optimal learning rate is non-trivial and cannot be determined by considering only the leading order terms in \( R \) as above, because although small \( \nu \) will result in a quicker escape from the unstable fixed point near \( R = 0 \) this will then lead to a very slow learning transient after escape.

From the above discussion one can draw two important conclusions. Firstly, the initial learning rate should be \( O(N^{-2}) \) or less initially in order to avoid trapping close to the initial conditions. Secondly, the time-scale required to escape the initial transient is \( O(N^3) \), resulting in an extremely slow initial stage of learning.

4.3 Other sub-optimal fixed points

In studies of other on-line learning algorithms, such as Sanger’s rule and back-propagation, a class of sub-optimal fixed points have been discovered which are due to symmetries inherent in the learning machine’s structure (Saad and Solla, 1995a; Biehl and Schwarze, 1995; Biehl and Schlößer, 1998). These symmetric fixed points are unstable for small learning rates, but the eigenvalues determining escape are typically of very small magnitude so that trapping can occur if the initial conditions are sufficiently symmetric. In practice this will typically occur only
for very large input dimensions \((N > 10^6)\) and will result in learning timescales
of \(O(N^2)\) for \(O(N^{-1})\) learning rates. Equation (8) does exhibit fixed points
of this type for particular initial conditions. Consider the case \(K = M = 2\) as an
example. If initially \(R_{11} \simeq R_{21}\) and \(R_{12} \simeq R_{22}\) then the dynamics will preserve
this symmetry until instabilities due to slight initial differences lead to escape from
an unstable fixed point. This symmetry breaking is necessary for good performance
since each projection must specialise to a particular source signal.

As mentioned above, sufficiently small differences in the initial value of the en-
tries in \(R\) will typically only occur for very large \(N\), much larger than the typical
values currently used in ICA. A very small learning rate is then required to avoid
trapping in a fixed point near the initial conditions, as discussed in the previous
section. This initial trapping is far more serious than the symmetric fixed point
since it requires a learning rate of \(O(N^{-2})\) in order to escape, resulting in a far
greater loss of efficiency. In practice, symmetric fixed points do not appear to be
a serious problem and we have not observed any such fixed points in simulations
of finite systems. This may be due to the highly stochastic nature of the initial
dynamics, in which fluctuations are large compared to the average dynamical tra-
jectory. This is in contrast to the picture for back-propagation, for example, where
fluctuations result in relatively small corrections to the average trajectory (Barber
et al., 1996). The strong fluctuations observed here may help break any symmetries
which might otherwise lead to trapping in a symmetric fixed point, although a full
understanding of this effect requires careful analysis of the multivariate diffusion
equation describing the dynamics near the initial conditions.

5 Simulation results

The theoretical results in the previous section are for the limiting case where \(N \to \infty\). In practice we should verify that the results are relevant in the case of large but
finite \(N\). In this section simulation evidence is presented which demonstrates that
the trapping predicted by the theory occurs in finite systems.

Figures 3(a)–(c) show results produced by an algorithm learning a single pro-
jection from 100-dimensional data with a single non-Gaussian (uniformly dis-
tributed) component \((N = 100, M = K = 1)\). The matrices \(A\) and \(W\) are
randomly initialised with orthogonal, normalised columns. Similar results are ob-
tained for other random initialisations. A cubic non-linearity is used and \(\sigma\) is set
to \(-1\), although the adaptive scheme for setting \(\sigma\) suggested by Hyvärinen and Oja
(1998) gives similar results. In each example, dashed lines show the maxima of
the potential in figure 2. Figure 3(a) shows the learning dynamics from a single
run with \(\eta = 10^{-5} (\nu = 0.1)\). The dynamics follows a relatively smooth tra-
jectory in this case and much of the learning is determined by the cubic term in equation (16). With this choice of learning rate there is a strong dependence on the initial conditions, with larger initial magnitude of $R$ often resulting in significantly faster learning. However, recall that a high value for $R$ cannot be chosen without prior knowledge of the mixing matrix. Figure 3(b) shows the learning dynamics with a larger learning rate $\eta = 10^{-4} (\nu = 1)$ for exactly the same initial conditions and sequence of data. In this case the learning trajectory is more obviously stochastic and is initially confined within the unstable sub-optimal state with $R \approx 0$. Eventually the system leaves this unstable state and quickly approaches $R \approx 1$. In this case the dynamics is not particularly sensitive to the initial magnitude of $R$ although the escape time can vary significantly due to the inherent randomness of the learning process. In figure 3(c) the learning dynamics is shown for a larger learning rate $\eta = 4 \times 10^{-4} (\nu = 4)$. In this case the system remains trapped in the sub-optimal state for the entire simulation time.

The analysis in section 4.2 is only strictly valid for the case of a single non-Gaussian source and a single projection. However, similar trapping occurs in general as demonstrated in figures 3(d)–(f). The components of $R$ are plotted for an algorithm learning two projections from 100-dimensional data with two non-Gaussian (uniformly distributed) components ($N = 100, M = K = 2$). The different learning regimes identified in the single component case are mirrored closely in the case of this two component model.

6 Conclusion

An on-line Hebbian ICA algorithm was studied for the case in which data comprises a linear mixture of Gaussian and non-Gaussian sources and a solution to the dynamics was obtained for the idealised scenario in which the number of non-Gaussian sources is finite while the number of Gaussian sources is infinite. The analysis confirmed the stability conditions found by Hyvärinen and Oja (1998) and the eigensystem characterising the asymptotic regime was determined. However, it was also shown that there exist sub-optimal fixed points of the learning dynamics which are stabilised by stochastic effects under certain conditions. The simplest case of a single non-Gaussian component was studied in detail. The analysis revealed that typically a very low learning rate ($\eta = O(N^{-2})$ where $N$ is the data dimension) is required to escape this sub-optimal fixed point, resulting in a long learning time of $O(N^3)$ iterations. Simulations of a finite system support these theoretical conclusions.

The sub-optimal fixed point studied here has some interesting features. In the limit $\eta \to 0$ the dynamics becomes deterministic and fluctuations due to the
stochastic nature of on-line learning vanish. In this case the sub-optimal fixed point is unstable but the Jacobian is zero at the fixed point (in the 1-dimensional case) indicating that one must go to higher order to describe the dynamics. Standard methods for describing the dynamics of on-line algorithms have all been developed in the neighborhood of fixed points with negative eigenvalues and are not applicable in this case (Heskes and Kappen, 1993). Furthermore, stability of the fixed point is induced by fluctuations. This is contrary to our intuition that fluctuations may be beneficial, resulting in quicker escape from sub-optimal fixed points. In the present case one has precisely the opposite effect: stochasticity stabilises an otherwise unstable fixed point. In similar studies of on-line PCA (Biehl and Schlösser, 1998) and back-propagation algorithms (Biehl and Schwarz, 1995; Saad and Solla, 1995a,b) sub-optimal fixed points have been found which are also stabilised when the learning rate exceeds some critical value. However, the scale of critical learning rate stabilising these fixed points is typically $O(N^{-1})$, much larger than in the present case. Also, the resulting time-scale for learning is $O(N^2)$ with a very small prefactor (in practice an $O(N)$ term will dominate for realistic $N$). These fixed points reflect saddle points in the mean flow while here we have a flat region and escape is through much weaker higher order effects. This type of sub-optimal fixed point is more reminiscent of those which have been found in studies of small networks, which often have a much more dramatic effect on learning efficiency (Heskes and Wiegerinck, 1998).

It is presently unclear whether on-line ICA algorithms based on Maximum-likelihood and Information-theoretic principles (see, for example, Amari et al., 1996; Bell and Sejnowski, 1995; Cardoso and Laheld, 1996) exhibit sub-optimal fixed points similar to those studied here. These algorithms estimate a square de-mixing matrix and will require a different theoretical treatment than for the projection model considered here, since there may be no simple macroscopic description of the system for large $N$.

A Derivation of the dynamical equations

From equation (5) one can calculate the change in $R$ and $Q$ (defined in (7)) after a single learning step,

$$
\Delta R = \eta \sigma \phi(y) s^T + \alpha (I - Q) R,
\Delta Q = \eta \sigma (I + \alpha (I - Q)) \phi(y) y^T + \eta \sigma y \phi(y)^T (I + \alpha (I - Q))
+ 2 \alpha (I - Q) Q + \alpha^2 (I - Q)^2 Q + \eta^2 \phi(y) x^T x \phi(y)^T. \quad (20)
$$

Here, the definition in equation (2) and the constraint in equation (4) have been used to set $x^T A_s = s^T$. One can obtain a set of differential equations in the limit $N \to \infty$ using a statistical mechanics formulation which has previously been applied to the dynamics of on-line PCA algorithms (Biehl, 1994; Biehl and Schlösser, 1998) as well as other unsupervised and supervised learning algorithms (see, for example, Biehl and Schwarze (1995); Saad and Solla (1995a,b) and contributions in Saad (1998)). To obtain differential equations one should scale the parameters of the learning algorithm in an appropriate way, in particular $\eta \equiv \mu / N$. Typically one chooses $\alpha = O(1)$ but in order to obtain an analytical solution it is more convenient to choose $\alpha = \alpha_0 / N$ before taking $N \to \infty$ and then take the limit $\alpha_0 \to \infty$. The dynamics do not appear to be sensitive to the exact value of $\alpha$ as long as $\alpha \gg \eta$ and it is therefore hoped that the dynamical equations are valid for $\alpha = O(1)$ which is usually the case. The learning rate is taken to be constant here but the dynamical equations are also valid when the learning rate is changed slowly, as suggested for the annealed learning studied in section 4.1.

As $N \to \infty$ one finds,

$$
\frac{dR}{d\tau} = \mu \sigma \langle \phi(y) s^T \rangle + \alpha_0 (I - Q) R, \quad (21)
\frac{dQ}{d\tau} = \mu \sigma \langle \phi(y) y^T + y \phi(y)^T \rangle + \mu^2 \langle \phi(y) \phi(y)^T \rangle + 2 \alpha_0 Q (I - Q). \quad (22)
$$
where \( \tau \equiv t/N \) is a rescaled time parameter. The angled brackets denote averages over \( y \) as defined in equation (8). In deriving the above equations one should check that fluctuations in \( R \) and \( Q \) vanish in the limit \( N \to \infty \). This relies on an assumption that \( R = O(1) \) which may not be appropriate in some cases. For example, in section 4.2 a sub-optimal fixed point is analysed where it is more appropriate to consider \( R = O(1/\sqrt{N}) \) and a more careful treatment of fluctuations is required.

As \( \alpha_0 \) is increased, \( Q \) approaches \( I \). If one sets \( Q - I \equiv q/\alpha_0 \) and make the \( \dot{a} \text{ priori} \) assumption that \( q = O(1) \) then,

\[
\frac{1}{\alpha_0} \frac{dq}{d\tau} = \mu \sigma \langle \phi(y)y^T + y\phi(y)^T \rangle + \mu^2 \langle \phi(y)\phi(y)^T \rangle - 2q + O(1/\alpha_0) .
\] (23)

As \( \alpha_0 \to \infty \) one can solve for \( q \),

\[
q = \frac{1}{2} \left( \mu \sigma \langle \phi(y)y^T + y\phi(y)^T \rangle + \mu^2 \langle \phi(y)\phi(y)^T \rangle \right),
\] (24)

which is consistent with the \( \dot{a} \text{ priori} \) assumption. Substituting this result into equation (21) leads to equation (9) in the main text. This is an example of adiabatic elimination of fast variables (Gardiner, 1985, section 6.6) and greatly simplifies the dynamical equations.

### B Eigensystem of asymptotic Jacobian

The Jacobian of \( dR/d\tau \) as \( \mu \to 0 \) is defined (divided by \( \mu \)),

\[
J_{ijkl} = \frac{\partial}{\partial R_{kl}} \left( \frac{1}{\mu} \frac{dR_{ij}}{d\tau} \right) \bigg|_{\mu=0}^{R=R^*} .
\] (25)

This is a tensor rather than a matrix because the system’s variables are in a matrix. One can think of pairs of indices \((i, j)\) and \((k, l)\) as each representing a single index in a vectorised system. If the dynamics is equivalent to gradient descent on some potential function then the above quantity is proportional to the (negative) Hessian of this cost function. The Jacobian is not guaranteed to be symmetric in the present case, so this will not be possible in general. From equation (21) one obtains,

\[
J_{ijkl} = -\delta_{ik} \delta_{jl} \left( \xi_i + \frac{1}{2} \xi_j \right) - \frac{1}{2} \delta_{il} \delta_{jk} \xi_i ,
\] (26)

with

\[
\xi_i = \begin{cases} 
\sigma_{ii} \langle s_i \phi(s_i) - \phi'(s_i) \rangle & \text{for } i \leq \min(K, M) , \\
0 & \text{otherwise} .
\end{cases}
\]
One must solve the following eigenvalue problem,

$$ \sum_{kl} J_{ijkl} V_{klnm} = \lambda_{nm} V_{ijnm} , $$

(27)

where \( \lambda_{ij} \) and \( V_{klij} \) are the eigenvalues and eigenvectors respectively. A solution is required for all \( i \leq K \) and \( j \leq M \) in order to get a complete set of eigenvalues,

\[
\begin{align*}
\lambda_{ii} &= -2\xi_i , \quad V_{klii} = \delta_{ik}\delta_{il} , \\
\lambda_{ij} &= -\frac{1}{2}(\xi_i + \xi_j) , \quad V_{klij} = \delta_{ik}\delta_{jl} - \delta_{jk}\delta_{il} \quad \text{for } i < j \leq K , \\
\lambda_{ij} &= -\xi_i , \quad V_{klij} = \delta_{ik}\delta_{jl} \quad \text{for } j > K , \\
\lambda_{ij} &= -(\xi_i + \xi_j) , \quad V_{klij} = \xi_i\delta_{ik}\delta_{jl} + \xi_j\delta_{jk}\delta_{il} \quad \text{for } i > j .
\end{align*}
\]
Figure 3: 100-dimensional data ($N = 100$) is produced from a mixture containing a small number of uniformly distributed sources. Figures on the left (a–c) are for a single non-Gaussian source and a single projection ($M = K = 1$) while figures on the right (d–f) are for two non-Gaussian sources and two projections ($M = K = 2$). Each column shows examples of learning with the same initial conditions and data but with different learning rates. From top to bottom: $\eta = 10^{-5}$ ($\nu = 0.1$), $\eta = 10^{-4}$ ($\nu = 1$) and $\eta = 4 \times 10^{-4}$ ($\nu = 4$).
