Mutations in both copies (homozygous or compound heterozygous) of the gene encoding the lysosomal enzyme glucocerebrosidase, which cleaves the glycolipid glucocerebroside into glucose and ceramide, cause Gaucher disease. However, multiple independent studies have also reported an association between GBA mutations and Parkinsonism with an increased frequency of heterozygous GBA mutations in various cohorts of patients with parkinsonism and other Lewy body disorders. Furthermore, GBA mutation carriers exhibit diverse parkinsonian phenotypes and present a diffuse pattern of Lewy body distribution in the cerebral cortex. This review provides an overview of the genetic basis for this association in various diseases with dysfunction of the central nervous system in which affected individuals developed Parkinsonian symptoms. The emerging clinical, pathological, and genetic studies in neuronal synucleinopathies suggest a common underlying mechanism in the etiology of these neurodegenerative disorders.

Keywords: glucocerebrosidase gene, Parkinson disease, synucleinopathies, Lewy body pathology

INTRODUCTION

GAUCHER DISEASE

Mutations in the glucocerebrosidase gene (OMIM #606463), which encodes the lysosomal enzyme glucocerebrosidase, which breaks down the glycolipid glucocerebroside (also called glucosylceramide) into glucose and ceramide, result in Gaucher disease (GD; Brady et al., 1965). This is the most common lysosomal storage disorder (LSD) and follows an autosomal recessive mode of inheritance. The accumulation of glucosylceramide primarily occurs in cells of the reticulo endothelial system. The classic cellular hallmark of Gaucher patients is the characteristic morphology of their macrophages with a “wrinkled tissue paper” appearance on cytoplasm, which contains lysosomal inclusion bodies, referred as Gaucher cells (Westbroek et al., 2011). These macrophages accumulate in the liver, spleen, and bone marrow, and patients can present with organomegaly (Beutler and Grabowski, 2001; Sidransky, 2004). Patients with GD can present with a broad range of phenotype and the spectrum of the disease correlates, at least in part, with residual enzyme activity (Cox and Schofield, 1997). Based on the age at onset and neurological manifestations, the disease is classified into three subtypes (type 1, OMIM #230800; type 2, OMIM #230900; and type 3, OMIM #2301000; Velayati et al., 2010). The most common phenotype is non-neuronopathic type 1, sometimes referred as “adult Gaucher disease,” although it can affect individuals of all ages. There is enough residual enzyme activity to prevent substrate storage in other cells rather than macrophages. Type 1 GD is relatively common in all ethnic groups, it presents the highest carrier frequency among Ashkenazi Jews population of 1 in 15 and an incidence of about 1 in 1,000. Although type 1 disease is traditionally considered non-neuronopathic, a subset of patients developed neurological alterations and subclinical peripheral neuropathy (Capablo et al., 2008). Patients with neuronopathic forms of the disease, present with either an acute course (type 2) or subacute course (type 3). Type 2 phenotype is the most severe form, often presenting in the first 6 months of life and the complete deficiency in glucocerebrosidase activity result in glucosylceramide accumulation in a variety of cell types, including neurons, which leads to rapidly fatal consequences either prenatally or shortly after birth (Cox and Schofield, 1997; Sidransky, 2004). Elevations in brain glucosylsphingosine have been detected in patients with neuronopathic GD, but not with type 1 (Orvisky et al., 2002). Type 3 tends to progress more slowly than type 2 and usually appears in adolescence. Affected individuals may survive into their 30 years. While not limited to any particular ethnic group, the largest group of patients with GD type 3 has been reported from the province of Norrbotten in Sweden (Dahl et al., 1990) and increased prevalence rates have also been reported in Japan and Spain. Although the GBA genotype plays a role in determining the type of GD, genotype-phenotype correlations are difficult to be established, due to the enormous clinical variation concerning the disease manifestations, clinical course, and response to therapy exhibited between patients who share the same genotype (Lachmann et al., 2004; Sidransky, 2004). Differences are even observed among siblings and twins (Amato et al., 2004; Lachmann et al., 2004).

GLUCOCEREBROSIDASE GENE (GBA)

The human GBA gene is located on chromosome 1q21 and is composed by 11 exons and 10 introns, spanning 7.6 kb of sequence. A highly homologous pseudogene (GBAP) is located 16 kb downstream and is 5.7 kb in length (Horowitz et al., 1989). The presence of this highly homologous pseudogene at the same locus, which shares 96% exonic sequence homology explains the high number of complex recombinant alleles between GBA and GBAP which have been detected in several GD, Parkinson’s disease (PD), or Lewy body dementia (LBD) patients (Hruska et al., 2008).
To date, approximately 300 pathogenic mutations scattered throughout the GBA gene have been reported and their frequency varies significantly according to the different ethnicity. For example, the common c.1226A > G (N370S) allele is quite frequent among patients of European, American, and Middle East origin and it is not seen in Chinese and Japanese cohorts. Moreover, this particular mutation accounts for approximately 70% of the mutant alleles in an Ashkenazi Jewish subjects with type 1 GD and with c.84dupG mutation accounts for about 10%. Therefore, focusing the mutation analysis only to these two mutations in Ashkenazi Jewish populations of GD type 1 could be considered a cost-effective procedure. However to other non-Ashkenazi Jewish populations, especially in patients with neuronopathic GD forms, the whole gene sequencing is required for an accurate genotyping (Hruska et al., 2008). Furthermore, to populations of European origin, two mutations, N370S and L444P contribute to two-thirds of the disease alleles found (Kaplan et al., 2006; Hruska et al., 2008). The allelic distribution of these two prevalent mutant alleles can be confused because many laboratories do not distinguish between the point mutation c.1448T > C (L444P) and recombinant alleles that include this mutation such as RecNcil (Hruska et al., 2008).

GAUCHER DISEASE AND PARKINSONISM

Clinical reports of patients with GD recognized a small subset of patients who develop parkinsonian symptoms including tremor, rigidity, and bradykinesia (Neudorfer et al., 1996; Machaczka et al., 1999; Bembi et al., 2003). In the majority of these cases, the onset of parkinsonian manifestations was noted in their 40 years, and cognitive changes had also occurred (Tayebi et al., 2003). Postmortem brain tissue of several of these subjects was examined, and Lewy bodies appeared in cortical areas corresponding to Braak stages 5–6, in addition to the classic PD pathology (Neumann et al., 2009). The substantia nigra showed a marked loss of pigmented neurons while numerous Lewy bodies were detected and were specifically associated with brain regions affected by GD, including the CA4–CA2 hippocampal regions (Wong et al., 2000, 2004). In order to investigate the underlying dopaminergic dysfunction in GBA mutation carriers with and without parkinsonism, Kono et al. (2010) used positron emission tomography (PET) and demonstrated presynaptic dopaminergic dysfunction in the GBA carriers with parkinsonism identical to PD.

Moreover, a higher frequency of PD has also been reported in relatives of patients with GD, many of whom were demonstrated to harbor a heterozygous mutation in GBA. Families of probands with GD were surveyed for the presence of PD among obligate GBA carriers, and a higher rate of PD has been observed compared to the putatively non-carriers cohort. These clinical observations, strengthen the association between these two disorders and provided evidence that mutant glucocerebrosidase, even in heterozygosity may be a risk factor for the development of parkinsonism (Goker-Alpan et al., 2004; Halperin et al., 2003). Furthermore, a recent study was able to estimate the PD penetrance in GBA mutation carriers. The authors considered GBA as a dominant causal gene with reduced penetrance which should be taken into consideration for genetic counseling in relatives of patients with GD and patients with GBA associated PD (Anheim et al., 2012).

GBA MUTATIONS IN PD COHORTS

The clinical observations of GD patients and their relatives prompted an examination of the GBA mutations among different cohorts of PD worldwide. The first description of the relationship between alterations in the GBA and PD has reported alterations in GBA in 12 (21%) autopsy samples of PD patients. These alterations were more frequent among the younger subjects. These included eight with mutations (N370S, L444P, K198T, and R329C) and four with probable polymorphisms (T369M and E326K; Lwin et al., 2004). Subsequently, the six GBA mutations (N370S, L444P, 844G, 1VS + 1, V394L, and R496H) which are most common among Ashkenazi Jews were screened for a clinic-based case series of 99 Ashkenazi patients with idiopathic PD and 1,543 healthy Ashkenazi Jews. Mutations were found in 31.3% of PD patients versus 6.2% of controls (P < 0.001). Once more, patients who were carriers of GBA mutations were younger than those who were not carriers (Aharon-Peretz et al., 2004).

Since then, multiple studies were conducted, in which these findings were replicated in various cohorts of PD patients with different geographical or ethnic origins. These studies reported higher GBA mutation frequencies among the Ashkenazi Jewish PD population, which varied in different centers, between 10.7 and 31.3% contrasting, with the lowest carrier frequency reported, 2.3% in a series of Norwegian patients with PD versus 1.7% in controls (Toft et al., 2006). To accurately ascertain the frequency of GBA mutations in Europe, several European non-Ashkenazi Jewish individuals with PD and ethnicity-matched controls were screened and GBA alterations have been found in 6.1% of Portuguese (Bras et al., 2009), 9.8% of Spanish (Setó-Salvia et al., 2011), 4.2% British (Neumann et al., 2009), 4.7% of Greek (Kalindrieri et al., 2009), 6.7% of French (Lesage et al., 2010), and 2.8% of Italian (De Marco et al., 2008). Importantly, some of the previous studies have focused the mutation analysis only in the two common mutations, N370S and L444P, whereas some others extended the mutations search to the entire coding region of the gene. Overall, the definitive study on this topic was published in 2009, when an international collaborative study of GBA mutations in PD patients was undertaken by pooling data for individual persons from 16 centers, in 12 countries, including 5,691 patients and 4,898 controls. The data collected demonstrated a strong association between GBA mutations and PD. This finding was not exclusive to a specific ethnic group or a specific GBA mutation. In addition, the age at onset of PD was found to be significantly lower among patients with GBA mutations as compared with those without mutations (P < 0.001; Sidransky et al., 2009).

Concordant results have been observed in familial PD cases. A large comprehensive study of all GBA exons in one patient with PD from each of 96 PD families selected, based on the family-specific lod scores at the GBA locus revealed nine different variants identified in 21 of the 96 PD cases (21.8%). These variants have been further tested in 1,325 PD cases from 566 multiplex PD families and in 359 controls and were present in 161 of these patients (12.2%) versus 5.3% of controls (Nichols et al., 2009). Similarly, a Japanese group identified eight multiplex PD families with patients with PD homozygous for pathogenic mutations in GBA (Mitsui et al., 2009). Therefore, it is conceivable that GBA
Almeida

Glucocerebrosidase and Parkinsonism

mutations underlie not only sporadic PD but also familial PD, and are associated with significantly earlier age at onset of disease.

**GBA MUTATIONS IN OTHER SYNucleinOPATHIES**

There is a line of evidence for the association of GBA mutations with other synucleinopathies rather than PD, such as dementia with Lewy bodies (DLB) and Lewy body variant Alzheimer disease (LBV-AD) but not in multiple-system atrophy (MSA).

Initially, Goker-Alpan et al. (2006) performed full genotyping of GBA in DNA from brain samples of 75 autopsy cases with pathologically confirmed Lewy body disorders including 28 PD, 35 cortical LBs (DLB or LBV-AD), and 12 MSA. Mutations in GBA gene were identified in 4% of cases with PD, 23% of cortical LBs, and none with MSA. A low frequency of GBA mutations, similar between cases (0.9%) and controls (1.2%) was also reported in a series of 108 British MSA pathologically confirmed cases and 257 controls (Neumann et al., 2009). Similarly, two additional studies did not identify GBA pathogenic mutations among MSA patients. One of the studies involved the sequencing of GBA in 27 MSA cases (Nishioka et al., 2011) and in the other one, the two most common mutations, L444P and N370S were tested in 66 MSA cases (Jamrozik et al., 2009). These data suggested a different mechanism to the α-synuclein aggregation in MSA cases in which its principal cellular target is the oligodendrocytes. The evolved concept that MSA may not just be related to PD but also share traits with the family of demyelinating disorders has been recently reviewed (Wenning et al., 2008).

As with the first study, an increased frequency of GBA mutations has also been detected in 2 (3.5%) of 57 clinical DLB patients of European Caucasian ancestry compared with control subjects (0.4%; Mata et al., 2008). In this latter study, only the two mutations, N370S and L444P were tested. Also, Farrer et al. (2009) reported mutations in GBA in 6% of 50 brain samples from subjects with pathologically confirmed diffuse LBD. Conversely, another study found GBA mutations in 28% (27 of 95) of patients with primary pathological diagnoses of LB disorders, compared with 10% (6 of 60) of cases with primary AD and 3% (1 of 32) of control cases (Clark et al., 2009). In this latter study, the presence of GBA mutations appeared to be related more to the presence of cortical LBs than to LBs confined to the subcortical regions. Moreover, GBA mutations were also detected in 6.8% (4/59) of cases with a pathological diagnosis of diffuse Lewy body disease. Taken with previous studies, it appears that GBA mutations are associated with a more diffuse pattern of Lewy body distribution involving the cerebral cortex than the brainstem/limbic distribution observed in typical PD (Nishioka et al., 2011). Also Setó-Salvia et al. (2011) reported more recently, 12% of LBD brains carrying a mutated GBA allele.

**GBA MUTATIONS AND COGNITIVE DECLINE**

Given the distribution of Lewy bodies into the neocortical regions, subsequently studies were conducted to rule out the influence of GBA mutations in the clinical course of PD, including cognitive decline and dementia. A prospectively evaluation at the NIH Clinical Center with detailed neurological examinations reported cognitive changes in half of the subjects (Goker-Alpan et al., 2008). In addition, the clinical features of a British PD patient group who carried GBA mutations comprised, an early-onset of the disease, the presence of hallucinations in 45% (14/31) and symptoms of cognitive decline or dementia in 48% (15/31) of the patients (Neumann et al., 2009). The effect of GBA on susceptibility to dementia was reinforced in Spanish PD patients with GBA mutations, in which half of the patients developed dementia during the clinical course of PD (Setó-Salvia et al., 2011).

**OTHER LYSOSOMAL STORAGE DISORDERS AND PARKINSONISM**

Glucocerebrosidase has been identified as a component of the Lewy body’s inclusions in patients with GBA mutations (Goker-Alpan et al., 2010) and it colocalized with lysosomal-associated membrane protein 1 (LAMP1) marker, which suggested an impairment of the lysosomal activity in LB pathology. This observation is supported by the emerging reports of PD across a range of LSDs. Over two-thirds of LSDs involve central nervous system dysfunction (progressive cognitive and motor decline) whereas affected individuals developed frequently parkinsonism with deposits of α-synuclein in the brain and substantia nigra pathology (Shachar et al., 2011; Schultz et al., 2011). For the first time, it was recently demonstrated accumulation of the α-synuclein in the cortical tissue of two postmortem cases of Sanfilippo syndrome (mucopolysaccharidosis type III, MPSIII; Winder-Rhodes et al., 2012). MPSIII is an autosomal recessive neurodegenerative storage disease caused by mutations in N-acetylgalactosaminidase (NAGLU) gene. Additional case reports of LSDs have described parkinsonism features among patients and in postmortem tissues, Lewy body’s inclusions have been observed. Thus, patients with GM1 gangliosidosis (caused by defective β-galactosidase activity), GM2 gangliosidoses, including Tay–Sachs and Sandhoff diseases (caused by defective β-hexosaminidase activity) and Fabry–Anderson disease (caused by the defective activity of α-galactosidase) as well as some family members, developed various PD symptoms including bradykinesia, rigidity, and resting tremor (Argov and Navon, 1984; Inzelberg and Korczyn, 1994; Orimo et al., 1994; Muthane et al., 2004; Roze et al., 2005).

Also relatives and patients with Niemann–Pick C disease (caused by the defective activity of either NPC1 or NPC2) presented with parkinsonian tremor and an α-synucleinopathy in human NPC brain was observed in the midbrain and amygdala of a postmortem tissue (Saito et al., 2004). Therefore, the link of PD and LSDs suggested a common underlying mechanism compromising the lysosomal and proteasomal degrading systems, resulting to the α-synuclein pathology shared by several of these disorders (Settembre et al., 2008). This association, as described above is not limited exclusively to changes that occur in GD, such as changes in glucocerebrosidase activity or in glucosylceramide levels, but rather include changes that might be common to a wide variety of LSDs. So it may be interesting in a near future to investigate the frequency of mutations in genes encoding lysosomal proteins in the patients who display Parkinson’s symptoms.

**GBA MUTATIONS AND CERAMIDE METABOLISM**

Although GBA mutations and consequently glucocerebrosidase deficiency show a clear and, potentially direct risk association with α-synucleinopathies and PD, it was suggested that this link is
due to its subtract accumulation, glucosylceramide excess, rather than the decrease levels of its subproduct, ceramide. Several studies have been conducted and no evidence of ceramide deficiency has been detected in patients with GD, even in those severely affected. This finding supported the existence of a tightly regulated ceramide levels resultant from many different degradative and synthetic pathways. So, the link between GBA heterozygosity and PD or other synucleinopathies may not be determined by ceramide metabolism dysfunction. In fact, the use of inhibitors of the glucocerebrosidase function has been shown to modulate α-synuclein levels (Manning-Bog et al., 2009). In addition, the α-synuclein aggregation and glucosylceramide accumulation occurred in a chemically induced glucocerebrosidase deficiency. These studies demonstrated a relationship between glucosylceramide accumulation and α-synuclein aggregates, and implicate glucosylceramide accumulation as risk factor for the α-synucleinopathies (Xu et al., 2010). Nevertheless, it was proposed that the abnormal α-synuclein pathology presented in neurodegeneration with brain iron accumulation 1 and 2 (NBAI-1, NBAI-2) caused by mutations in the pantothenate kinase type 2 (PANK2) and phospholipase A2, group VI (PLA2G6) genes, respectively, could be connected to ceramide metabolism (Bras et al., 2008). However, very recently, it was demonstrated that PLA2G6 mutations were the second common genetic cause after PARK2 gene mutation in cohorts of Chinese and Taiwanese young-onset parkinsonism with Chinese ethnicity (Shi et al., 2011; Lu et al., 2012). Additionally, the postmortem study on a series of patients with PLA2G6 mutations, demonstrated widespread α-synuclein positive Lewy pathology particularly severe in the neocortex (Paisán-Ruiz et al., 2012). Therefore, in order to rule out the pathogenic mechanism by which, mutations in PLA2G6 gene cause PD, it will be interesting to measure the ceramide levels in these early-onset PD patients carrying mutations in the PLA2G6 gene.

POSSIBLE MECHANISMS LINK GBA AND PD AND α-SYNUCLEINOPATHIES

GBA mutations act as a strong risk factor to α-synucleinopathies and Parkinson disease interfering with the clearance of or promote the aggregation of α-synuclein. Mazzulli et al. (2011) have shown that intracellular glucosylceramide levels control the formation of soluble toxic α-synuclein assemblies in cultured neurons and mouse and human brain, leading to neurodegeneration. The elevation and formation of α-synuclein assemblies inhibits the lysosomal activity of normal glucocerebrosidase in neurons and idiopathic PD brain, resulting in additional glucosylceramide accumulation and augmented α-synuclein oligomer formation. This self-propagating positive feedback process, proceeds until a pathogenic threshold is reached, resulting in neurodegeneration (Mazzulli et al., 2011). The frequently reported lysosomal proteolytic dysfunction in PD as well as in other LSDs is one of the common mechanisms underlying the α-synuclein pathology shared by various of these disorders (Shachar et al., 2011; Yap et al., 2011). Indeed, the disruption of autophagy-lysosomal process has been proposed as the mechanism by which LRRK2 mutations, the gene responsible for the autosomal dominant forms of PD, may exert its effects (Tong et al., 2010). The autophagy degrading pathway is considered the primary mechanism through which α-synuclein is degraded and its impairment is reinforced by the involvement of another gene associated with familial forms of PD, ATP13A gene, which encodes a lysosomal ATPase responsible for maintaining intralysosomal pH and suppresses α-synuclein toxicity in C. elegans, yeast, and primary neuronal cultures (Gitler et al., 2009). In addition, the dysfunction of the ubiquitin–proteasome system also underlies many of these α-synucleinopathies. Again, Parkin gene which has been associated mostly with the early-onset PD recessive familial cases encodes the E3 ubiquitin ligase, and is involved in the ubiquitination pathway of misfolded glucocerebrosidase in dopaminergic neurons. The absence of normal parkin leads to improper degradation of some of its substracts, such as α-synuclein and to their accumulation (Ron et al., 2010).

A distinct α-synuclein degraded pathway within lysosomes is the chaperone mediated autophagy (CMA), whereas SNCA mutants Ala53Thr and Ala30Pro bind to LAMP2A but fail to translocate into the lysosomal lumen for breakdown (Cuervo et al., 2004; Cullen et al., 2011). Subsequently, further CMA-mediated degradation substrates are blocked, which contributes to their accumulation (Westbroek et al., 2011). Likewise, defects in mitochondrial activity are reported in many of α-synucleinopathies which results mainly in decrease levels of the ATP synthesis, causing the formation of free radicals leading to oxidative stress and impairment of the membrane potential (Schapira, 2011). Several studies have demonstrated the effect of PD causative genes also on mitochondrial depolarization and their interference in the electron transport chain (Schapira and Gegg, 2011).

Additionally, GBA haploinsufficiency alters the lipid metabolism and composition of the cell membranes which is also considered a common impaired pathway in many of these disorders. The helical binding of α-synuclein to lipid membranes prevents the formation of fibrillar protein structures. It has been demonstrated that α-synuclein does bind to brain-derived glycosphingolipids that contain glucosylceramide in their core. Therefore, deficiency of glucocerebrosidase leads to the accumulation of its substrates glucosylceramide and/or glucosylsphingosine and alter sphingolipid composition of the cell membranes, which may disrupt the membrane binding of α-synuclein, enhancing its aggregation in the cytoplasm (DePaolo et al., 2009).

In this article, an extensive literature review has documented clinical, pathological, and genetic studies which have contributed to our growing understanding of the involvement of the glucocerebrosidase as a susceptibility factor to PD and other synucleinopathies. The rapid pace of investigation of the GBA function has been stimulated by the identification of mutations in this gene, not only in GD patients, but also in sporadic and familial PD cohorts as well as in different α-synucleinopathies. The clinical and pathological studies have accompanied and complement the genetic analysis of GBA gene in different patient’s cohorts, adding a crucial value toward the delineation of the different molecular pathways underlying the pathogenesis of these conditions. Curiously, an attempt to integrate the different molecular pathways and functions in a unique mechanism indicates a considerable overlap between them, suggesting interactions of pathological proteins engaging common downstream pathways which is not only relevant for the familial forms, but also to the more common sporadic PD cases.
