A Signal Processing Method for Text Language Identification

H. Hassanpour, M. M. AlyanNezhadi, M. Mohammadi

Abstract

Language identification is a critical step prior to any natural language processing. In this paper, a signal processing method for Language Identification is proposed. Sequence of characters in a word and the order of words in stream identify the language. The sequence of characters in a stream provides a signature to recognize the language without understanding its meaning. The signature can be extracted using signal processing techniques via converting texts into time series. Although several research and commercial software have been developed to identify text language, they need a standard dictionary for each language. We proposed a dictionary independent method consisting of three main steps, I) preprocessing, II) clustering and finally III) classification. First, the texts are converted to time series using UTF-8 codes. Second, to group similar languages, the obtained series are clustered. Third, each cluster is decomposed into 32 sub-bands using a Wavelet packet, and 32 features are extracted from each sub-band. Also, a multilayer perceptron neural network is used to classify the extracted features. The proposed method was tested on our dataset with 31000 texts from 31 different languages. The proposed method achieved 72.20% accuracy for language identification.

1. INTRODUCTION

Natural language processing (NLP) techniques play an important role in the classification and processing of huge digital documents on the Web [1, 2]. Determination of the language of a text's content is called Language Identification (LID classification). This is the initial step in many NLP pipelines such as tagging data stream from Twitter with relevant language, improving search results by searching in the relevant language, and automatically using machine translation [3]. Since most of the later steps are language-dependent, any errors in the first step is compounded by later steps. Although the determination of disjoint languages is not a tough task, distinguishing the languages originated from the same root (e.g., Persian and Arabic or Italian and English) is a difficult task.

The ability to identify the language of a document increases the accessibility of data. It has a vast range of applications, i.e., presenting information in a user’s native language is critical in attracting website visitors [4]. Most of the text processing techniques presuppose that the document's language is known. However, in real-world data, automatic LID is required to identify the language of the document.

The rhythm of expression is different in languages. It is created by the sequence of letters. Therefore, in this study, we will use the sequence of letters to identify the language. Of course, due to cultural and political issues, words from languages such as English, Arabic and French have infiltrated other languages. This makes language identification a bit difficult.

In the proposed method's training phase, the text is converted into a time series using UTF-8 coding. The time series is clustered into different clusters then analyzed using the Wavelet packet. The statistical features are extracted from each sub-band and used as the inputs of a multilayer perceptron neural network.

The proposed method is examined with our collected dataset. The provided dataset covers similar languages.
Designing a system to distinguish between similar languages such as Serbian and Croatian [5], language varieties like European Portuguese and Brazilian [6], or a set of Arabic dialects [7] is more challenging than designing systems to discriminate between, for example, Finnish and Japanese [8, 9]. The experimental results show the ability of the proposed method for LID with a similar languages dataset.

The rest of the paper is organized as follows. In the next section, we review several litterateurs dealing with LID, then the proposed method is described. In Section 3, our dataset is introduced, and applying the proposed method to the dataset is given. Finally, the study is concluded in section 4.

2. LITERATURE REVIEW

Some approaches have been proposed in literature for LID based on frequent word counting, unique tokens and n-gram [3] in which features such as the presence of particular characters, words or n-grams [10] are used as discriminators.

In the case of frequent words counting [11], the language is identified based on the frequencies of the words in the predefined dictionary constructed per each language. Another approach is based on n-gram. The n-gram is a contiguous sequence of items from a given text. There are some words with higher frequency for each human language than others, which can be used as discriminator feature. Ng and Selamat [12] studied three n-grams based identification method, i.e., distance measurement, Boolean technique and optimum profile technique. In the first method, the profiles are produced and sorted based on n-gram frequencies. The minimum distance between testing and training profiles is selected as the winner. In the Boolean technique, the matching rate between testing and training profiles is computed. The language of the text is identified based on the highest matching rate. The first approach suffers from dimensionality problem and the latter fails in the case of the same n-gram frequency for multiple languages. The last approach applies both frequency and position features. The language with minimum converged point is known as the text language [12].

Common words such as conjunctions, determiners, and prepositions can be used to extract LID features. Dunning [13] used byte level n-grams of the entire string instead of the word's character level n-grams. Although n-gram based methods provide high accuracy in LID, but these methods suffer from high order of time complexity [14].

N-gram based methods are the most common LID methods in the literature. Several methods in combination with this approach have been developed, like SVM [15], Naïve Bayes [16], prediction partial matching (PPM) [17], deep learning [18] and a combination of multiple classifier [19]. There are also benchmarking solutions to the LID. Google compact language detector (CLD) and TextCat employ n-gram based method, LogR [20] uses a discriminative strategy with regularized logistic regression [16]. Cavnar and Trenkle [14] provided outstanding results compared to the other state-of-the-art methods. They used rank order statistic as distance measure. The weakness of this method is that it relies to the tokenization while many languages have no boundaries.

The languages with the same origin are very similar in appearance and n-grams. For example, Arabic and Persian languages are of the same origin. As shown in Figure 1, they are very similar to each other. As can be seen in Equation (1), 50% of 2-grams (bigrams) from the two example texts are joint. In addition, 59% and 76% of the two sample texts, the Persian and Arabic are existed in intersection of 2-grams sample texts (Equations (1) and (2)). Therefore, the n-gram based approaches are unable to distinguish between these languages.

\[
\frac{\text{bigram}_{\text{Persian}} \cap \text{bigram}_{\text{Arabic}}}{\text{bigram}_{\text{Persian}} \cup \text{bigram}_{\text{Arabic}}} = \frac{29}{58} = 0.5
\]

(1)

\[
\frac{\text{bigram}_{\text{Persian}} \cap \text{bigram}_{\text{Arabic}}}{\text{bigram}_{\text{Persian}}} = \frac{29}{49} = 0.59
\]

(2)

\[
\frac{\text{bigram}_{\text{Persian}} \cap \text{bigram}_{\text{Arabic}}}{\text{bigram}_{\text{Arabic}}} = \frac{29}{38} = 0.76
\]

(3)

Various LID systems exist in literature for identifying text language but with a limited number of languages to identify. Shekhar et al. [21] and Gupta et al. [22] proposed an LID system to recognize Hindi and English languages.

After a rigorous search we found no prior study that employed signal processing techniques to identify the language of a text. In this paper, we address the problem of LID from a signal processing perspective. Different languages have different tones. Someone can recognize the language of a conversation if has previously heard such a conversation, even tough he/she does not understand the concept. Different languages show different frequency characteristics. This fact also can be observed from the text indicating correspondent phrases in a language. For each language, there is a dependency between components of a sentence as well as components that construct the word. These dependencies can be observed using both Fourier transform and Wavelet transform methods. The Fourier transform is not a good choice as it provides more diversity for the spectrum representation of the texts from the same language.

Figure 1. Samples of Persian and Arabic texts. As can be seen these languages are very similar to each other both in appearance and 2-grams

3. THE PROPOSED METHOD

Difference between languages is mainly due to their tunes. A language’s tune depends on the succession of letters in a word and the pronunciation of successive words in a statement. Once we listen to a speech, we initially recognize the language and subsequently understand its meaning depending on the language’s grammar. We may not fully understand a speech with a low volume level or low Signal to Noise (SNR) ratio, but we can still recognize the language spoken in if we know the language.

Once a French speaker talks English, the English speech is understandable even with a French accent. Indeed, speech in a language is a succession of letters that construct a tune. We propose a signal processing technique to convert text to time series and extract the tune for language identification. The flowchart of the algorithm is depicted in Figure 2.

In the proposed method, texts are converted to time series. The texts can be converted to time series using suitable coding. All texts in our dataset are coded with UTF-8. Characters such as @, # and + may exist in different texts. Therefore, they are removed from the time series. The obtained signal is clustered into several clusters using K-means method. The only feature for clustering is the mean of the signals UTF-8 codes. Some languages having unique UTF-8 codes are clustered in groups with only one language per group. However, the languages with similar UTF-8 codes appear in the same cluster. Thus, further processing is required to detect the language of texts in each cluster. To this aim, for each cluster, a model is trained and tested. The steps for the training are: I) feature extraction and II) classification.

**Feature Extraction:** The clustered signals are analyzed using the Wavelet packet transform, which is an extension of the Wavelet transform provided with more information regarding both high and low-frequency bands of the signal. By using the Wavelet packet transform, each signal is decomposed into 32 sub-bands.

The median of partial energy related to the sub-band coefficients is extracted from each sub-band as a feature.

\[ F_x = \log(\text{median}(x^2)) \]

where, \( x \) is the sub-band coefficients. This feature is used for language identification introduced by Alyan-Nezhadi et al. [23].

**Classification:** Many techniques in literature employ neural networks in their classification [24-26]. In this paper, the extracted features are fed into multilayer perceptron neural network with one hidden layer and the network is trained to classify the languages. For testing a new text, first, the cluster of the text is determined. If the cluster contains only one language, that language will be assigned to the text. Otherwise, the correspondent model will be used to detect the language in the cluster.

4. DISCUSSION AND RESULTS

In the following first, we describe the dataset we have prepared, then the obtained results are discussed.

4.1 Dataset

We have selected 31 languages to assess the performance of the proposed method. For each language, 1000 texts were randomly extracted from Wikipedia. The minimum length for each text is 5000 characters. The languages include English (en), France...
4. Evaluation  

To evaluate the performance of the proposed method, we used 31000 texts from our dataset. 80% of the texts are used for clustering, training and validation, and the remaining 20% of texts is used for testing randomly. The texts are converted to time series using UTF-8 coding and then the common characters are removed from them.

In the first stage, the K-means is used to cluster the whole data into six clusters based on only one simple feature (the average of the signals after elimination of common characters in the time domain). Table 1 shows the clustered languages in six groups with group centers and clustering precisions. As shown in Table 1, the texts with languages Tamil and Hindi are identified in this step with accuracy 90.50% and 95.50% for the testing dataset.

The average accuracy of 95.14% is achieved for six clusters with the centers: 1246.56, 878.73, 1370.18, 2820.96, 1874.38, 107.67 for testing data.

The obtained centers are used to cluster the test data. In the second stage, the texts from each cluster are separately classified. To this aim, the training texts (without elimination of common characters such as '?', '.', '!') are analyzed and decomposed using the Wavelet packet transform into 32 sub-bands. We have selected the Wavelet packet transform to analyze the texts. We employ a Wavelet packet transform with Daubachies kernel and five levels of decomposition. The Daubachies kernel is selected as it has valuable characteristics, i.e., vanishing moment and orthogonality conditions. We focussed on the sub-band energy to extract a feature as the classical multidimensional scaling (CMDS) representation of sub-band energy shows a separable cluster of different languages. This fact is shown in Figure 3 for seven languages from the dataset. The CMDS is a geometrical representation of data structure. Experimentally, we observed that the magnitude of the median provides more discrimination than the mean feature. We applied the logarithm to the median's magnitude to expand the distance between the languages with a close feature.

The multi-layer perceptron neural network with the parameters specified in Table 2; which is used to classify the languages based on the extracted features. The network has 32 input nodes as the length of the feature vector is 32. The number of neurons in the hidden layer is set equal to input layer. The network is trained 10 times and the results are averaged because the MLP may provide different results with different initial point. Table 3 shows the classification results for different states where 5, 7, and 12 spaces are inserted in between two consecutive words of testing dataset. Finally, the accuracy of the system (clustering and classification) is given in Table 4. Figure 4 shows the structure of the experiment.

| TABLE 1. Clustering the data into six clusters |
|-----------------------------------------------|
| Cluster members | Cluster centre | Accuracy (%) |

5. CONCLUSION

LID plays an important role in most of the text processing applications. As this task is the first step to almost any text processing technique, the errors made in this task will propagate and deteriorate the results in the latter stages. In this paper, a new signal processing based technique was proposed to identify the text languages without any dictionary necessity. The proposed method includes the preprocessing, clustering, feature extraction, and classification stages. The proposed method was tested on our dataset with 31 different languages. Similar languages with the same origin exist in our dataset. The accuracy of 72.20% was achieved for text language identification.
