INFLAMMATION OF THE SKIN

I. PHOSPHOLIPID METABOLISM IN SOME EXPERIMENTAL INFLAMMATIONS OF MOUSE SKIN

Abstract—Phospholipid metabolism in inflamed tissue of the mouse skin which had been induced by the application of 1-chloro-2, 4-dinitrobenzene (DNCB), croton oil, or irradiation of ultraviolet rays was examined, and it was found that phospholipid levels had increased in the inflamed tissues. In the case of ultraviolet rays, the increase was temporary, and the level returned to that of control after 3 or 4 days. In the case of DNCB or croton oil, the level increased after a decrease for a short period. The pattern of the increase between physical and chemical irritation was different. Increase of incorporation of 32P into phospholipid in inflamed tissue was examined, and it was observed that the level reached a maximum after one day. It is thus assumed that phospholipid plays an important role in the mechanism of inflammation.

Dasher and Hilliser, Bole et al., and Bole (1-3) suggested that phospholipid metabolism in the skin was transformed by inflammation, however, the role of phospholipid metabolism in inflammation is very complex. It has been well established that phospholipids play an important role in ion transport as one of cell membrane components. Normally, concentration of sodium ions in cells is lower than that in sero-fluids, as a result of the "sodium pump mechanism". This active transport moreover depends on ATPase which is activated by the phospholipids (4). There is a report (5) that corticosteroid inhibits the production of ATP in local skin inflammation, and it was of interest to study the role of phospholipid in the local skin inflammation. According to Spector's theory (6, 7), histamine, one of the most popular chemical mediators, is activated by an enzyme in the surface membrane of mast cells. Aizawa and Iwasaki (4) reported that phospholipid levels rose before an increase in weight of inflamed muscle tissues induced by implantation of cotton threads. Activity of ATPase contained in sarcolemma also increased.

In the present work, phospholipid level or the incorporation of 32P into phospholipid was measured on inflamed tissues of mouse skin after application of 1-chloro-2, 4-dinitrobenzene (DNCB), croton oil, or irradiation of ultraviolet rays.

MATERIALS AND METHODS

Male albino mice of dd strain weighing about 20 g were provided a commercial diet (CLEA Japan Inc., Tokyo) for 1 week before the experiment and were weighed daily. Five

Part of this work was presented at the 6th Congress of International Federation of Societies of Cosmetic Chemists, Barcelona, September, 1970.
healthy animals were selected to form a group. All solvents used for extraction of phospholipids and proteins were reagent grade. A mercury lamp (300 W. Fuji Roentogen Inc., Tokyo) was constructed and adjusted so that the mice subjected to the rays could be placed as close as Tcm from the lamp.

**Induction of experimental skin inflammation:** Hair in an area of about 2 × 2 cm² on the back of a mouse was clipped as short as possible using an electric hair clipper 1 day before the experiment. Ultraviolet rays from a mercury lamp were irradiated on the mouse for 10 min from a distance of 7.0 cm. A mouse was fixed and covered by a dark green sheet with an opening of 2 × 2 cm² over the clipped area. DNBC was dissolved in a mixture of chloroform and olive oil (1:1) to contain 0.1 g/ml. A solution of 0.05 ml was dropped on the clipped area, and the solution was allowed to spread over the skin. After the chloroform had evaporated naturally, the olive oil was left on the skin as an adhesive of DNBC. Croton oil was dissolved in a mixture of ethanol and chloroform (3:1) to contain 0.25 g/ml, and 0.05 ml of this solution was applied in a similar way. For the controls, the solvent without DNBC or croton oil was applied.

**Extraction and determination of phospholipid and protein:** The mice were sacrificed on 6 hr, 1, 2, 4, 8, and 12 days after the treatment respectively, and about 100 mg of dorsal skin was removed. The skin was homogenized in 6 ml of 5% cold trichloroacetic acid solution. The homogenized tissue was placed in a 15-ml centrifuge tube and centrifuged (at 3000 rpm). The sediment was washed 3 times with 3 ml each of cold trichloroacetic acid solution. Phospholipids were then extracted from the sediment with 3 ml of 80% ethanol and chloroform-ethanol (1:1), and twice with 3 ml of ether. All extracts were combined and diluted with mixed solvent to 15 ml in a volumetric flask. An aliquot of 2 ml of this extract solution was pipetted into a borosilicate glass test tube and was evaporated to dryness with a stream of air below 60°C. After 0.3 ml of 70% perchloric acid was added, the tube was heated until the liquid became clear. Inorganic phosphorus was determined by the method of Chen et al. (8). After the extraction of lipids, the residue was suspended in 3 ml of 2% sodium hydroxide solution and heated in a boiling water bath for 5 min. Proteins soluble in alkali were extracted, and this process was repeated twice. All the extracts were combined, diluted with water to 20 ml in a volumetric flask, and 0.2 to 0.4 ml of the extract solution was pipetted into a test tube. Protein was determined by the method of Lowry et al. (9).

**Incubation:** After the dorsal skin was cleansed with ethanol, mice were sacrificed on 1, 3, 7, and 12 days after the treatment respectively, and about 100 mg of the skin was removed. The removed tissues were incubated at 37°C for 2 hr in a stream of standard oxygen gas (95% O₂/5% CO₂). The incubation medium was Krebs-Ringer bicarbonate solution (pH 7.4) which contained 0.1% of glucose and 50 µCi/ml of radioactive orthophosphate (H₃²PO₄). At the end of the incubation period, the tissue was washed twice with 5 ml of cold isotonic sodium chloride solution. The phospholipids were extracted by the method mentioned above. Radioactivity in the phospholipid was determined (with 1.5 ml of the extracts) by Geiger-Müller counter.
RESULTS

As shown in Table 1, inflammation induced by ultraviolet rays did not change the phospholipid level per wet weight of the tissue but increased its level per mg protein. The maximum level of the phospholipid per mg protein was observed at 6 hr after the treatment in which the value showed 190% to the control, but this level began to decrease after 1 day. After 4 days, the level had returned to the control level. After 8 days, the phospholipid level reversed, became less than that of the control, and then began to return gradually. In contrast, the level of phospholipid per wet weight of tissue changed little.

| Treatment | Inorganic phosphorus in phospholipid (μg) | Days after treatment |
|-----------|------------------------------------------|---------------------|
| UV rays   | 37.2 ± 1.3 | 40.7 ± 1.2 | 34.6 ± 1.2 | 38.8 ± 1.3 | 38.7 ± 0.5 | 38.5 ± 8.6 | 37.9 ± 2.0 |
|           | 2.31 ± 0.21 | 4.31 ± 0.31 | 3.42 ± 0.09 | 3.24 ± 0.45 | 2.45 ± 0.27 | 1.97 ± 0.18 | 2.16 ± 0.36 |
| DNCB      | 29.9 ± 0.4 | 11.9 ± 0.9 | 24.5 ± 2.4 | 30.9 ± 0.7 | 34.7 ± 1.4 | 38.8 ± 1.8 | 31.6 ± 1.7 |
| Croton oil| 2.54 ± 0.04 | 2.17 ± 0.06 | 3.18 ± 0.24 | 3.27 ± 0.12 | 3.04 ± 0.13 | 3.01 ± 0.31 | 3.30 ± 0.21 |

Values are means ± S.E.

On the other hand, inflammation induced by DNCB markedly decreased the phospholipid level per wet weight of tissue for a short period. The minimum level was 40% of the control. Inflammation by DNCB was different from that by ultraviolet rays in so far as the phospholipid level per mg protein decreased in the same as that per wet weight of tissue. After 1 day, both levels began to increase. An increase in phospholipid level per mg protein reached an earlier peak after 2 days, and the level was 130% of the control. The level per wet weight of tissue increased slowly and reached a maximum after 8 days. The maximum level was 130% of the control. In the case of inflammation by DNCB, restoration to the normal level required a longer period, and the level per mg protein was still 130% of the control after 12 days.

In the case of croton oil, decrease of phospholipid level per wet weight of tissue, as in the case of DNCB, was observed for a short period, but the decrease per mg protein was hardly observed. Increase of water in inflamed tissue was observed clearly for a short period. The increase of phospholipid then became more remarkable than that of water after 1 day, and increased gradually to 180% of the control after 12 days. Such an increase of phospholipid over a long period indicates different patterns of inflammation according to the inducing method.
In order to determine synthetic patterns of phospholipid in inflamed skin tissues which varied by the method of induction, the tissues were incubated with radioactive inorganic phosphate (Table 2). In the case of ultraviolet rays, incorporation of $^{32}$P into phospholipid was increased and its level was 160% of the control after 1 day. The level decreased for the following few days and then returned to the control level after 7 days. In the case of DNCB, an increase in the incorporation reached the maximum after 1 day, the same as in the case of ultraviolet rays, and returned to the control level after 7 days. In either case, an increase in the incorporation of $^{32}$P was observed at an earlier period of inflammation, but the increase in incorporation was not always parallel to the increase in phospholipid level.

**DISCUSSION**

Although there are many methods of inducing inflammation, only a few can be applied to the skin. In the present work, two patterns in the increase of phospholipid level were observed following chemical irritation, DNCB or croton oil, and ultraviolet rays.

According to Matthews et al. (10), the level of phospholipids in the skin tissue is 0.7 to 0.8% of dry tissue, but there are considerable differences in each tissue. Kopenhoefer (11) reported that the lipid phosphorus distribution in the skin of the steer is 0.0% in the hair, 0.031% in the basal epidermal region. Taylor et al. (12) found that in healing skin wounds of rats, the phospholipid included about 30% of total lipids in the stage of most rapid healing, as compared with approximately 3% in normal skin tissue. Bole et al. (2) reported that lipid or phospholipid level of inflamed tissue which had been induced by subcutaneous implantion of polyvinyl alcohol sponge was increased and sometimes decreased. Furthermore, Bole (3) reported that inflamed tissue which had been induced by the same method was incubated with $^{32}$P-orthophosphate and $^{14}$C-glycerol, and the results showed a definite difference in the labeling patterns of $^{32}$P and $^{14}$C. Aizawa and Iwasaki (4) reported that phospholipid metabolism rose before an increase in weight of inflamed muscle tissue. Thus phospholipids together with ATPase appears to play an important role in the mechanism of inflammation. According to Johnson and Mier (13), the level of phospholipid in the mouse skin was decreased by *in vitro* irradiation of ultraviolet rays.

---

**Table 2. Radioactivity of phospholipid in inflamed skin tissue**

| Treatment | cpn | Days after treatment |
|-----------|-----|----------------------|
|           |     | Control 1 3 7 12     |
| UV rays   |     | per $\mu$g phosphorus $251 \pm 36$ $338 \pm 70$ $313 \pm 62$ $221 \pm 50$ $236 \pm 28$
|           |     | per mg protein       $659 \pm 48$ $1128 \pm 59$ $838 \pm 63$ $643 \pm 67$ $670 \pm 23$
|           |     | per 100 mg wet tissue $64 \pm 3$ $124 \pm 26$ $112 \pm 14$ $71 \pm 7$ $80 \pm 6$
|           |     | per $\mu$g phosphorus $360 \pm 46$ $529 \pm 60$ $298 \pm 40$ $360 \pm 27$ $378 \pm 19$
| DNCB      |     | per mg protein       $1771 \pm 89$ $1937 \pm 123$ $1859 \pm 302$ $2001 \pm 101$ $1029 \pm 203$
|           |     | per 100 mg wet tissue $92 \pm 1$ $115 \pm 9$ $80 \pm 9$ $93 \pm 8$ $87 \pm 4$

violet rays, but the level of \(^{32}\)P incorporated into phospholipid was increased by in vivo irradiation. They assumed that phospholipid decomposed by ultraviolet rays, but synthetic reaction of phospholipid in the skin was accelerated by the stimulative action of ultraviolet rays. It is still a matter of discussion whether this change is a primary chemical reaction or a reaction of inflammatory mechanism. According to the present data, phospholipid level increased not only by ultraviolet irradiation but also by DNBC or croton oil. In both cases, the amount of radioactive phosphorus incorporated into phospholipid from inorganic orthophosphate (\(\text{H}_3\text{PO}_4\)) was increased.

Thus, it may be assumed that, even if the phospholipid is decomposed with ultraviolet irradiation, inflammation accelerates the synthetic reaction of phospholipid in the skin tissue. If such is the case, then phospholipids do play an important role in the mechanism of inflammation. The increase of phospholipid level varied according to the method of inducing inflammation, and the result of ultraviolet irradiation was different from that after application of chemicals. The increase in the former case was temporary and the amount of radioactive phosphorus increased simultaneously, but the phospholipid level per wet weight of tissue increased slightly. These facts indicate that the synthesis of phospholipid is increased by inflammation. It is known that phospholipids play an important role in cell membrane, one of these roles being the active transport of ions. Matsuyama (14) and Nohara (15) reported that inflammation decreased potassium ions and increased sodium, calcium, and magnesium ions in the skin tissue. Investigation is now underway to determine the relationship between phospholipid increase and the change in ion ratio.
