Abstract:
Formation of fistulous connection between great saphenous vein graft and pulmonary vasculature after coronary artery bypass graft (CABG) is a rare event, which can result in recurrence of symptoms ranging from stable angina to myocardial infarction related to coronary steal phenomenon. We hereby report a case of a 63 years old man who was detected to have such a fistulous communication leading to coronary steal syndrome as the cause of effort angina 12 years after CABG. Coronary angioplasty and stenting of left anterior descending artery resulted in resolution of symptoms.

Key words: Angina, Angioplasty, Coronary Artery Bypass, Myocardial Infarction, Saphenous Vein.

Introduction
Formation of fistulous connection between saphenous vein grafts and pulmonary vasculature after coronary artery bypass graft (CABG) is a rare event, which can be asymptomatic or result in recurrence of symptoms ranging from stable angina to myocardial infarction related to coronary steal phenomenon [1,2].

Case Report
A 63 years old man underwent CABG 12 years ago for multiple lesions involving proximal and distal left anterior descending artery (LAD), common right coronary artery (RCA) and marginal coronary artery. Bypass consisted of reversed saphenous vein graft (RSVG) to RCA, RSVG to marginal coronary artery, RSVG to LAD and left internal mammary artery (LIMA) to diagonal coronary artery. Patient had a postoperative bleeding for which he was operated again with successful control of the bleeding. He was symptom-free for the next 12 years. 12 years later, he presented with exertional angina and a positive stress test for which he was taken for cardiac catheterization.

The RSVG to RCA and the LIMA to diagonal branch were normal. Left anterior descending artery angiography showed a stenosis of 75%-80% distal to the anastomosis with multiple fistulous communications between the saphenous vein graft
and the left upper lobe pulmonary vein via pleural vessels [Fig.1]. There was angiographic evidence of coronary steal phenomenon with decreased antegrade flow in the distal part of left anterior descending artery. We concluded that the degree of coronary steal on top of the distal stenosis was significant enough to cause coronary ischemia.

Considering the presence of multiple fistulous communications between the saphenous vein graft and the pulmonary vasculature with the distal stenosis, coil occlusion of feeders was not considered. Instead, the patient underwent coronary angioplasty with stent implantation (stent Cypher 2.5x13 mm) to the distal lesion in left anterior descending artery with good result [Fig.2]. He is symptom-free at 5 years of follow up.

Discussion

The evolution of the internal mammary artery and the saphenous vein grafts in the coronary artery bypass surgeries still has lots of secrets to understand. The formation of fistulous connection between those grafts and the pulmonary vasculature, many years after the coronary artery bypass graft (CABG), is a rare event. Those fistulas can vary widely in their anatomy. Cases of internal mammary fistulas to pulmonary vein, pulmonary artery, pulmonary parenchyma and even coronary vein have been reported [3,4]. The cases of saphenous veins fistulas have been more frequently associated with aneurysmal veins communicating with pulmonary vessels or cardiac chambers [5].

The pathogenesis of these fistulas is not fully understood. Several etiologies have been proposed. It is usually secondary to coronary revascularization, trauma, inflammation, infection or neoplasia [6]. Some case reports suggest that it is related to electrocoagulation instead of clipping the internal mammary artery [7]. It is also suggested that the inflammatory response from disruption of the pleura during surgery and subsequent neovascularization can lead to multiple communications between grafts and pulmonary vasculature [8].

When symptomatic, the events associated with those fistulas are caused by a coronary steal phenomenon [1]. This phenomenon, resulting in
ischemia, is due to a hemodynamically significant shunt. When a coronary stenosis appears distally to a fistula it can aggravate the problem even more. To verify the presence of a coronary steal syndrome, we should look into the symptomatic status, angiography, demonstration of ischemia by radionuclide studies and most specifically by Doppler flow wires. The symptoms associated with the coronary steal syndrome can range from stable angina to acute coronary syndrome and contribute significantly to morbidity. Excessive shunt may result in volume overload of ventricle leading to cardiac failure, depending upon magnitude of shunt. Excessive shunt can be quantified by oximetry or assessed indirectly using echocardiography for presence of volume overload of ventricle.

The best strategy to manage this condition depends on the gravity of the problem. Many options has been described in the English literature: surgical ligation of all the collateral channels [9], percutaneous occlusion of the feeding channels using coils [10,11] or conservative medical management [1]. However we felt that the component of coronary ischemia alone needs to be addressed if the shunt is not hemodynamically significant and further sternotomy can be avoided. In our case, stenting of the native coronary vessel percutaneously revealed to be a good option to treat the vein graft to pulmonary artery fistula. To our knowledge, native vessel percutaneous coronary intervention as a treatment strategy for fistula causing coronary steal phenomenon has only been reported once [12].

**Conclusion**

In conclusion, the formation of fistulous connection between the saphenous vein grafts and the pulmonary vasculature are considered as late complications post CABG. They are very rare to occur but should be recognized as a possible cause of recurrent angina. The optimal therapeutic strategy is still controversial.
